Risk of Colorectal Cancer in Patients with Acute Myocardial Infarction and Stroke: A Nationwide Cohort Study

Rune Erichsen¹, Claus Svarke¹, Henrik T. Sørensen¹², Robert S. Sandler², and John A. Baron¹²

Abstract

Background: An association between colorectal cancer and acute myocardial infarction (AMI) and stroke has been suggested, but evidence is conflicting.

Method: We conducted a population-based cohort study (1978–2010) of the association between AMI/stroke and colorectal cancer by linking nationwide Danish registries. We calculated standardized incidence ratios (SIR) of colorectal cancer after AMI/stroke as the ratios of observed to expected incidence.

Results: A total of 297,523 patients with AMI (median age, 69.4 years; 64% men) were followed for a median of 3.1 years (range, 0–33 years) and 4,387 developed colorectal cancer (SIR, 1.08; 95% confidence interval (CI), 1.05–1.11; P < 0.001). In the first year of follow-up, the SIR was 1.85 (95% CI, 1.73–1.98; P < 0.001), whereas it was 0.98 (95% CI, 0.95–1.02; P = 0.318) in the second and subsequent years. We followed 246,998 patients with stroke (median age, 72.4 years; 52% men) for a median of 2.9 years (range, 0–33 years) and 3,035 developed colorectal cancer (SIR, 1.04; 95% CI, 1.00–1.07; P = 0.053). In the first year of follow-up, the SIR was 1.42 (95% CI, 1.31–1.53; P < 0.001), whereas it was 0.96 (95% CI, 0.93–1.00; P = 0.072) thereafter. We found no difference between the SIRs for ischemic and hemorrhagic stroke. The increased one-year relative risks for AMI and stroke corresponded to a 0.3% absolute risk.

Conclusions: Our findings reflect detection of occult cancer at the time of the vascular event. The lack of increased risk after one year suggests that an association based on shared risk factors or chronic inflammation is unlikely.

Impact: In patients with AMI/stroke, the diagnostic workup including screening for colorectal cancer should follow that of the general population. Cancer Epidemiol Biomarkers Prev; 22(11); 1994–9. ©2013 AACR.

Introduction

In westernized countries, the lifetime risk of acute myocardial infarction (AMI) and stroke is 30% to 40% and 15% to 20% (1, 2), respectively, whereas the lifetime risk of colorectal cancer is approximately 5% (3). The early development of all these diseases seems to involve chronic inflammation, which is known to be crucial in the atherosclerotic process, particularly in unstable plaques (4, 5) and may also be important in colorectal cancer carcinogenesis (6–11). AMI, stroke, and colorectal cancer also share some risk factors such as smoking, obesity, metabolic syndrome, and diabetes, all of which have been associated with systemic inflammation (12–14).

Evidence of an association between atherosclerosis and colorectal neoplasia was recently emphasized by a small cross-sectional study from Hong Kong showing a higher prevalence of advanced neoplasia in patients with proven coronary artery disease (>50% stenosis in any one of the major coronary arteries) than among patients whose angiograms did not show coronary artery disease (18.4% vs. 8.7%) (15). Nonetheless, the nature of the association is not clear. Existing studies of the relation between coronary artery disease or AMI/stroke and colorectal cancer have been conflicting, with some confirming the association (6, 7, 15–19), and others not finding it (20–24). The presence of atherosclerosis (a chronic pathologic condition) is conceptually different than the occurrence of AMI or stroke (acute clinical events; refs. 6, 7, 15, 22) characterized by unstable plaques prone to rupture (25). Therefore, studies of atherosclerosis may not be generalizable to patients with AMI/stroke.

If an association between AMI/Stroke and colorectal cancer really exists, it may foster the understanding of the etiology of these diseases and could also be relevant for screening and surveillance for patients with these common and lethal diseases. Therefore, we used the nationwide population-based Danish databases to conduct the largest cohort study of colorectal cancer risk in patients with AMI and stroke to date.

Materials and Methods

We conducted this cohort study in the setting of the entire Danish population, which, in the study period January 1, 1978 to December 31, 2010, included 8.0 million people. The Danish National Health Service provides tax-funded medical care for all Danish residents and maintains clinical databases describing the care provided. All Danish residents are assigned a unique 10-digit civil registration number by the Civil Registration System at birth or immigration, an identifier routinely used to link patients across the various Danish medical databases (26).

Data sources and cohort

We identified patients with AMI and stroke (≥30 years of age) by extracting relevant inpatient diagnoses from the National Registry of Patients (NRP), which has tracked all nonpsychiatric hospitalizations in Denmark since 1977 and outpatient hospital contacts since 1995. The NRP records the civil registration number, dates of admission and discharge, and up to 20 discharge diagnoses, coded by physicians according to the International Classification of Diseases (ICD; 8th revision until the end of 1993 and 10th revision thereafter). Patients were enrolled in the study cohort if they had ICD codes corresponding to AMI or stroke (see Supplementary Table S1). From the NRP, we also extracted information on comorbid diseases diagnosed before or at the time of AMI or stroke diagnosis: diabetes, chronic obstructive pulmonary disease, rheumatoid disease, venous thromboembolism, obesity, hyperlipidemia, hypertension, atrial fibrillation, and transient ischemic attack (see Supplementary Table S1). Finally, we included information on colonoscopies conducted before or on the date of the AMI/stroke. Of note, there is no population colorectal cancer screening in Denmark.

Using the civil registration number, we linked all members of the study cohort to the nationwide Danish Cancer Registry (DCR). The DCR has recorded all incident malignant neoplasms in Denmark since 1943. Its data include month and year of cancer diagnosis and tumor spread at diagnosis (localized, regional, metastasized, or unknown). Cancers are classified according to ICD-10 codes (see Supplementary Table S1). Patients diagnosed with any cancer before date of AMI and stroke were excluded.

Statistical analyses

We calculated the proportion of patients with AMI and stroke within categories of demographic characteristics. The follow-up period for cancer occurrence began at the date of AMI and stroke diagnosis and ended at the date of colorectal cancer diagnosis, emigration, death, or December 31, 2010, whichever came first. The number of colorectal cancer cases observed among the study subjects was compared with the number expected on the basis of cancer rates calculated from the DCR. The expected number was calculated by multiplying the number of person-years of observation for study subjects by the national colorectal cancer incidence rates for each sex in 1-year age groups. Standardized incidence ratios (SIR) were calculated as the ratio of the observed to the expected number of colorectal cancer cases (27). The statistical methods assumed that the observed number of cases in any specific category followed a Poisson distribution. Confidence intervals (CI) for the SIR were calculated on the basis of Byar’s approximation; exact confidence limits were used if the observed number of cases was less than 10.

We calculated SIRs for patients with AMI and stroke overall and for patients with ischemic and hemorrhagic stroke separately. SIRs were stratified by sex, age, year of AMI/stroke diagnosis, and follow-up interval (first year of follow-up and second and subsequent years). In a sub-analysis, we further categorized follow-up into 0–6 months, 6–12 months, 12–24 months, 2–5 years, 5–10 years, 10–15 years, and 15+ years. We also calculated SIRs in patients with AMI and stroke with prior colonoscopy and coexistence of each of the comorbidity diseases listed earlier. As for the overall analysis, these analyses were standardized according to sex, age, and calendar period. In a subanalysis, we calculated SIRs for colon and rectal cancers separately. In addition, we estimated absolute risks of colorectal cancer 1, 5, and 10 years after AMI and stroke diagnosis, treating death as competing risk (28).

Finally, we evaluated whether colorectal cancers were diagnosed at an earlier or later stage in patients with AMI or stroke than among patients with colorectal cancer without these diseases. We did this by matching each patient with colorectal cancer with a history of AMI or stroke by age, gender, and year of diagnosis to 5 patients with colorectal cancer from the general population without history of AMI/stroke. We calculated proportions and associated 95% CIs by dividing the proportion of localized, regional, and metastatic colorectal cancers in patients with an AMI and stroke history with the proportions in matched colorectal cancer patients with no history of these diseases.

Results

AMI

We identified 297,523 patients with AMI, of whom 64% were men (Table 1). They had a median age at diagnosis of 69.6 years and were followed for a median of 3.1 years (range, 0–33 years). A total of 4,387 patients with AMI were recorded with a colorectal cancer diagnosis during follow-up, corresponding to an overall SIR for colorectal cancer of 1.08 (95% CI, 1.05–1.11; Table 2). Women and individuals more than 80 years of age at the time of AMI had the highest SIRs. Concomitant diabetes, chronic obstructive pulmonary disease, obesity, hypertension, or atrial fibrillation was associated with particularly increased risk of colorectal cancer. A total of 7,750 (2.6%) patients had a colonoscopy before AMI diagnosis and their SIR of colorectal cancer was similar to the overall result. The SIR for 1978 to 1983 was 1.35 (95% CI, 1.21–1.51), whereas it was close to 1.0 in the most recent periods.

The SIR for colorectal cancer was increased only in the first year after AMI diagnosis (1.85; 95% CI, 1.73–1.98 vs.
As compared with the second and subsequent years (Fig. 1). The SIRs in the first year of follow-up were increased in both men (1.72; 95% CI, 1.57–1.87) and women (2.11; 95% CI, 1.89–2.35) throughout the study period (results by year not shown).

Even though the SIR was increased in the first year after AMI diagnosis, the absolute risk of colorectal cancer after AMI was only 0.3% (95% CI, 0.3%–0.3%). By 5 and 10 years after diagnosis, the absolute risk had increased only to 0.8% (95% CI, 0.7%–0.8%) and 1.2% (95% CI, 1.1%–1.3%).

Comparing the 840 patients with colorectal cancer diagnosed within 1 year after AMI with 4,200 matched colorectal cancer patients without history of AMI, the proportion ratios were 46%/41% = 1.1 (95% CI, 1.0–1.2) for localized colorectal cancer, 26%/27% = 0.9 (95% CI, 0.8–1.1) for regional spread colorectal cancer, and 17%/20% = 0.8 (95% CI, 0.7–1.0) for metastatic colorectal cancer. For colorectal cancers diagnosed more than 1 year after an AMI and their matched comparators, the corresponding proportion ratios were 43%/41% = 1.1 (95% CI, 1.0–1.1), 26%/26% = 1.0 (95% CI, 0.9–1.1), and 19%/21% = 0.9 (95% CI, 0.8–1.0), respectively.

**Stroke**

A total of 243,998 patients with stroke, with a median age at diagnosis of 72.8 years, were followed for a median of 2.9 years (range, 0–33 years); 52% were men (Table 1). During follow-up, 3,035 patients had a colorectal cancer diagnosis, corresponding to an overall SIR of 1.04 (95% CI, 1.00–1.07; Table 2). The SIRs were similar in men and women and over calendar periods, although the SIR decreased with increasing age. As expected, the coexistence of chronic obstructive pulmonary disease, obesity, or atrial fibrillation was associated with increased risk of colorectal cancer. Among the 10,716 (4.3%) patients with colonoscopy before stroke diagnosis, the SIR was similar to the overall result.

As for patients with AMI, the SIR of colorectal cancer in patients with stroke was increased in the first year after diagnosis (1.42; 95% CI, 1.31–1.53), but not in the second and subsequent years (0.96; 95% CI, 0.93–1.00; Fig. 1). The SIR of colorectal cancer within the first year of diagnosis was increased in both men (1.45; 95% CI, 1.31–1.60) and women (1.37; 95% CI, 1.22–1.54) throughout the study period (results by year not shown).

The subanalysis for patients with ischemic and hemorrhagic stroke is shown in the Supplementary Table S2 and revealed no major differences in SIRs.

The absolute risk of colorectal cancer after 1 year of a stroke diagnosis was 0.3% (95% CI, 0.3%–0.3%); the 5- and 10-year absolute risks were 0.8% (95% CI, 0.8%–0.9%) and 1.3% (95% CI, 1.2%–1.4%), respectively.

Finally, comparing the 663 patients with colorectal cancer diagnosed within 1 year after stroke with 3,314 matched colorectal cancer patients without history of stroke, the proportion ratios were 40%/41% = 1.0 (95% CI, 0.9–1.1) for localized colorectal cancer, 26%/26% = 1.0 (95% CI, 0.9–1.1), and 18%/21% = 0.9 (95% CI, 0.7–1.0), respectively.

**Discussion**

In this Danish nationwide cohort study of 297,523 patients with AMI and 243,998 with stroke, we found an increased risk of colorectal cancer in the first year of follow-up, but no increased risk thereafter. The increased
relative risks for AMI and stroke corresponded to a 1-year absolute risk of only 0.3%. As expected, the relative risk was highest in patients with known colorectal cancer risk factors such as diabetes and obesity coexisting with AMI/stroke. Cancer stage at diagnosis in AMI/stroke patient was virtually identical to patients with colorectal cancer with the same gender, age, and diagnosis year without AMI/stroke.

Our results are supported by other AMI/stroke studies finding no overall association with colorectal cancer, although these either excluded the first year of follow-up or did not evaluate first and subsequent years separately (20, 21, 23). In contrast, several previous studies have supported a relation between AMI/stroke and colorectal cancer (16–18). However, these studies are inconsistent with regard to which gender shows the effect and whether colon or rectal cancer risk is involved. None of them examined risks over time since AMI/stroke diagnosis, and the modest relative risks observed are quite compatible with the pattern we found: an increase in the first year and none thereafter. For example, a Swedish regional study (17), found that male patients were at increased colon cancer risk (SIR 1.13; 95% CI, 1.01–1.26), but female patients were not. Similar results were found in a 2001 Israeli cohort study including only men (risk ratio of 1.18, 95% CI, 1.18–1.29; ref. 18). In addition, a 2005 follow-up study of 110,972 Japanese, which used data on past history of AMI and stroke from baseline self-administered questionnaires, found an increased rectal cancer risk in female patients with AMI (only 49 patients with rectal cancer, HR, 1.16)

*Comorbid diseases were diagnosed before or at date of AMI or stroke diagnosis. The observed incidence of colorectal cancer in patients with AMI/stroke and the relevant comorbid disease was compared with the expected age- and gender-specific incidence in the overall background population.
with hemorrhagic stroke, not treated with antithrombotics, thrombolytic, or aspirin treatment prescribed to patients not clearly find. It is conceivable that the antithrombotic, however, more early-stage cancers among patients with increasing diagnostic testing. If this bias were profound, hospitalized and then placed under close observation, of diagnostic bias, as patients with AMI and stroke are (29, 30). Finally, the increased risk may merely be the result plastic syndrome caused by the (occult) colorectal cancer the clinical manifestation of a hypercoagulable paraneo-
cipitating AMI, or stroke. Second, AMI and stroke could be occult bleeding from the tumor may cause anaemia, pre-
AMI and stroke could have several explanations. First,
the increased colorectal cancer risk in the first year after the study, whereas the relative risk in the first year of
among patients with AMI was highest in the early years of
AMI/stroke and colorectal cancer association by separat-
ing the first year of follow-up from the subsequent years,
making clear that the relationship is likely not due to shared risk factors or common etiologic pathways.

Colorectal cancer risk has also been studied in patients with stable atherosclerotic (stenosis) who have not experi-
enced acute events such as AMI or stroke. At least two
cross-sectional studies (7, 15) and one case–control study (6) have reported an association, whereas a population-
based case–control (20) and a cohort study (22) did not. However, the underlying pathology behind AMI and ischemic stroke may differ from that of stable atheroscle-
rosis (25).

The overall relative risk of colorectal cancer particularly among patients with AMI was highest in the early years of the study, whereas the relative risk in the first year of follow-up remained elevated throughout the study period.
The increased colorectal cancer risk in the first year after AMI and stroke could have several explanations. First, occult bleeding from the tumor may cause anaemia, precipi-
tating AMI, or stroke. Second, AMI and stroke could be the clinical manifestation of a hypercoagulable paraneo-
plastic syndrome caused by the (occult) colorectal cancer (29, 30). Finally, the increased risk may merely be the result of diagnostic bias, as patients with AMI and stroke are hospitalized and then placed under close observation, increasing diagnostic testing. If this bias were profound, however, more early-stage cancers among patients with AMI and stroke would be expected, a pattern which we did not clearly find. It is conceivable that the antithrombotic, thrombolytic, or aspirin treatment prescribed to patients with AMI and ischemic stroke at diagnosis could cause an asymptomatic colorectal lesion to present as gastroin-
testinal bleeding. However, were this the case, patients with hemorrhagic stroke, not treated with antithrombotics,

3.05; 95% CI, 1.28–7.28) but also a nonsignificant increased risk of rectal cancer in female patients with stroke (HR, 2.99, 95% CI, 0.72–12.45; ref. 16).

Our data therefore clarify previous research on the AMI/stroke and colorectal cancer association by separat-
ing the first year of follow-up from the subsequent years, making clear that the relationship is likely not due to shared risk factors or common etiologic pathways.

Colorectal cancer risk has also been studied in patients with stable atherosclerotic (stenosis) who have not experi-
enced acute events such as AMI or stroke. At least two
cross-sectional studies (7, 15) and one case–control study (6) have reported an association, whereas a population-
based case–control (20) and a cohort study (22) did not. However, the underlying pathology behind AMI and ischemic stroke may differ from that of stable atheroscle-
rosis (25).

The overall relative risk of colorectal cancer particularly among patients with AMI was highest in the early years of the study, whereas the relative risk in the first year of follow-up remained elevated throughout the study period.
