The \textit{PALB2} Gene Is a Strong Candidate for Clinical Testing in \textit{BRCA1}- and \textit{BRCA2}-Negative Hereditary Breast Cancer

Marketa Janatova\textsuperscript{1,} Zdenek Kleiblo\textsuperscript{1}, Jana Streinova\textsuperscript{1}, Ales Panczak\textsuperscript{2}, Kamila Vesela\textsuperscript{2}, Martina Zimovjanova\textsuperscript{4}, Petra Kleiblova\textsuperscript{1,2}, Pavel Dundr\textsuperscript{3}, Jana Soukupova\textsuperscript{1}, and Petr Pohlreich\textsuperscript{1}

Abstract

\textbf{Background:} Several reports indicate that inherited mutations in the \textit{PALB2} gene predispose to breast cancer. However, there is little agreement about the clinical relevance and usefulness of mutation screening in this gene. We analyzed the prevalence and spectrum of germline mutations in \textit{PALB2} to estimate their contribution to hereditary breast and/or ovarian cancer in the Czech Republic.

\textbf{Methods:} The entire \textit{PALB2} coding region was sequenced in 409 breast/ovarian cancer patients negative for \textit{BRCA1} and \textit{BRCA2} mutations. Testing for large genomic rearrangements (LGR) was performed by multiplex ligation-dependent probe amplification (MLPA) analysis.

\textbf{Results:} We have identified 13 different pathogenic alterations including 10 truncating mutations and three LGRs in 16 of 409 patients (3.9%), whereas one truncating mutation was found in a group of 1,226 controls (0.08%; \(P = 2.6 \times 10^{-9}\)). Three novel LGRs included deletions involving exons 7–8 and 9–10, respectively, and a duplication spanning exons 9–11. Five frameshift and two nonsense mutations were novel, whereas three truncating mutations were described previously. The only recurrent mutation was the c.172_175delTTGT detected in four unrelated breast cancer individuals.

\textbf{Conclusions:} Our analyses demonstrated the significant role of the \textit{PALB2} gene in breast cancer susceptibility. The highest frequency of \textit{PALB2} mutations (comparable with that previously reported for \textit{BRCA2}) was found in a subgroup of patients with hereditary breast cancer (HBC) (13/235; 5.5%).

\textbf{Impact:} Our results show that mutation analysis of the \textit{PALB2} gene, including the analysis of LGRs, is primarily indicated in patients with HBC in case of their \textit{BRCA1} and \textit{BRCA2} negativity. \textit{Cancer Epidemiol Biomarkers Prev; 22(12): 2323–32. ©2013 AACR.}

Introduction

Mutations in the \textit{BRCA1} and \textit{BRCA2} genes represent the most important genetic risk factors for hereditary breast cancer (HBC). In the Czech Republic, the germline mutations in these two breast cancer genes account for approximately 3% of unselected breast cancer cases and about 23% of familial breast cancer cases (1, 2). Mutations identified in other breast cancer–susceptibility genes, \textit{ATM} (3), \textit{CHEK2} (4), \textit{TP53} (5), and \textit{NBN} (6), were significantly less frequent and together were responsible for about 3% to 4% of patients with familial breast cancer. These results indicate that mutations in other relevant genes may be involved in genetic susceptibility to breast cancer.

The \textit{PALB2} protein (partner and localizer of \textit{BRCA2}) was described as a binding partner of the \textit{BRCA2} protein, essential for its function in DNA double-strand break repair (7). It also binds to \textit{BRCA1} and mediates the interaction between \textit{BRCA1} and \textit{BRCA2} (8, 9). The \textit{PALB2} gene (OMIM# 610355) was recently identified (10) as a Fanconi anemia (FA) gene (known as \textit{FANCN}). Its biallelic mutations cause Fanconi anemia subtype N with a phenotype similar to that (FA-D1) caused by biallelic \textit{BRCA2} mutations. Studies performed in the United Kingdom (11) and Finland (12) demonstrated that monoallelic mutations in \textit{PALB2} predispose to breast cancer. Five different \textit{PALB2} mutations in 10 of 923 (1.1%) individuals with familial breast cancer were found in the United Kingdom. A founder \textit{PALB2} c.1592delT mutation, associated with a roughly 4-fold increased hereditary propensity for female breast cancer, was detected in Finland in 3 of 113 (2.7%) patients with familial breast cancer and in 18 of 1,918 (0.9%) unselected breast cancer cases. Until now, about 50 truncating mutations have been detected in breast cancer families worldwide (11–32) and mutations have also been reported in cases of inherited pancreatic (33–35) and ovarian cancer (18, 36). Therefore, \textit{PALB2} has been identified in four unrelated breast cancer individuals.
considered a strong candidate breast cancer–susceptibility gene; however, due to the limited number of studies, estimation of penetrance of breast cancer associated with \( \text{PALB2} \) mutation has not been precisely determined (37). The population of the Czech Republic and other countries in the Central Europe was not screened for \( \text{PALB2} \) mutations.

We sequenced the entire coding region of the \( \text{PALB2} \) gene in a group of patients with high-risk \( \text{BRCA1} \)- and \( \text{BRCA2} \)-negative breast/ovarian cancer. The purpose of the study was to characterize the spectrum of \( \text{PALB2} \) mutations and to estimate their contribution to the development of inherited breast and ovarian cancer.

**Materials and Methods**

**Characteristics of high-risk breast cancer patients, unselected breast cancer patients, and controls**

In total, 409 patients with high-risk breast and/or ovarian cancer negatively tested for the presence of pathogenic mutations in \( \text{BRCA1} \) and \( \text{BRCA2} \) genes in our institute between 2000 and 2010 were selected for this study (Table 1). The analyzed group included 330 familial cases and 79 cases without reported family history of cancer (referred to herein as nonfamilial cancer cases). Familial cases met the following criteria in first- or second-degree relatives: two cases of either breast cancer diagnosed before the age of 50 years or ovarian cancer diagnosed at any age; and three or more cases of breast cancer or ovarian cancer diagnosed at any age; and patients with primary breast and ovarian cancer. The average \( \text{BRCA-PRO} \) (38) risk estimates for each group of patients are given in Table 1.

The unselected breast cancer group included DNA samples from 704 consecutive female patients with breast cancer. These patients were treated at the Department of Oncology, General University Hospital in Prague (Praha, Czech Republic) between 2004 and 2006 and were included into the study regardless of the age at diagnosis and breast cancer family history. The average age of breast cancer diagnosis in this group was 56.5 years (range, 27–93 years) and the majority of samples involved patients with ductal and lobular histologic subtypes (72% and 11%, respectively).

The control group consisted of DNA samples obtained from 1,226 individuals involving 756 noncancer individuals and 470 blood donors described previously (4, 39).

All patients and controls were of a Czech origin and were living in the Prague area. The study was approved by the Ethical Committee of the First Faculty of Medicine and the General University Hospital and all participants gave their written informed consent with the use of stored DNA/RNA samples for research purposes.

**Mutation analysis**

Genomic DNA and total RNA from peripheral blood samples of high-risk individuals was isolated using standard extraction methods as described previously (40). The mutation analysis of the \( \text{PALB2} \) coding sequence was based on cDNA sequencing. Total RNA was reverse transcribed into cDNA using an Expand Reverse Transcriptase kit (Roche) and random hexamers (Roche) according to the manufacturer’s instructions. The entire coding region corresponding to \( \text{PALB2} \) mRNA was divided into three overlapping fragments that were PCR-amplified. Amplifications were carried out in 10-\( \mu \)L reaction mixtures containing 1 \( \mu \)L 10 \( \times \) PCR buffer, 0.2 mmol/L of each dNTP, 0.4 \( \mu \)mol/L of each primer, 1 \( \mu \)L of cDNA template, and 0.5 U of Fast Start Taq DNA polymerase (Roche). Following the initial denaturation (at 95°C for 4 minutes), 35 cycles (at 95°C for 30 seconds, 60°C for 30 seconds, and 72°C for 2 minutes) and a final extension (at 72°C for 7 minutes) were performed. Primer sequences are listed in Supplementary Table S1. PCR products were purified with ExoSAP-IT (USB Corp.) according to the supplier’s instructions and sequenced using the BigDye Terminator v3.1 Cycle Sequencing Kit on an ABI 3130.

Each marker was amplified by PCR using FAM-labeled PALB2 on the telomeric side. The positions of the markers and the two markers (D16S417 and D16S420) flanking (D16S412) flanking cancer control group, negative for the presence of this carriers and 16 randomly selected samples from a non-
c.172_175delTTGT, we genotyped all identified mutation Genomic and protein sequences for Information (NCBI) reference sequence NM_024675.3.

Haplotype analysis
To define the origin of the recurrent PALB2 mutation c.172_175delTTGT, we genotyped all identified mutation carriers and 16 randomly selected samples from a non-cancer control group, negative for the presence of this mutation (27, 43). Haplotype analysis included marker (D16S412) flanking PALB2 on the centromeric side and two markers (D16S417 and D16S420) flanking PALB2 on the telomeric side. The positions of the markers and the PALB2 gene were obtained from NCBI (NT_010393.16). Each marker was amplified by PCR using FAM-labeled forward primers as described previously (3, 44) and analyzed on an ABI 3130 genetic analyzer with a Gene-Mapper v4.0 Software.

In vitro and in silico analyses
An in vitro protein truncation test (PTT) was performed to detect a premature termination of translation as a result of the dinucleotide change in the coding sequence of the gene (c.661_662delinsTA), leading to the generation of a stop codon. A PCR fragment encompassing the alteration was amplified with a forward primer containing the T7 RNA polymerase promoter, the Kozak translation initiation sequence, and a start codon (Supplementary Table S1). The PTT was performed as described previously (40).

BRCA1 and BRCA2 gene mutation probabilities were calculated using the BRCAPRO BayesMendel model with the CancerGene software package available at http://www4.utsouthwestern.edu/breasthealth/cagene/ (38). The pathogenicity of missense variants was assessed using the SIFT (sorts intolerant from tolerant; ref. 45), PolyPhen (46) and Align GVGD (Grantham Variation, Grantham Deviation) software (47).

Statistical analysis
Frequencies of mutations in different subgroups were compared using Fisher exact test.

Results
Analysis of PALB2 mutations in high-risk patients
To determine the prevalence of deleterious PALB2 mutations in the group of patients with high-risk cancer, we analyzed the entire PALB2 coding region by direct sequencing and MLPA screening. Ten different protein truncating mutations and three LGRs were identified in 16 of 409 (3.9%) participants (Table 2), whereas one mutation was observed in 1,226 controls (0.08%; P = 2.6 × 10 −9). In 330 familial cases, 13 mutations were found in a subgroup of 235 families (5.5%) with a history positive for breast cancer only (HBC families), whereas no mutation was detected in 95 cases from families with a history positive for breast cancer and ovarian cancer or for ovarian cancer only (P = 0.02). In 79 high-risk nonfamilial patients, one carrier of the PALB2 mutation was detected in a group of 22 male patients with breast cancer (4.5%), one in a group of 39 patients with bilateral breast cancer (2.6%), and one in a group of 18 patients with both breast and ovarian cancer (5.6%; Table 1).

The only recurrent mutation was the c.172_175delTTGT deletion found in four unrelated families. Other mutations distributed widely across the coding sequence of the gene were observed only once and included six frameshift mutations (c.509_510delGA, c.901_907delT, c.1227_1231del5, c.1924delA, c.1942_1945delICTTAin-sAAC, and c.35b2delG) and two nonsense mutations (c.73A>T and c.1240C>T). The c.661_662delinsTA variant represented the dinucleotide change. A shorter protein product obtained from the patient’s DNA by a PTT analysis confirmed that bases GT 661-662 substituted

to TA were located on the same allele of the PALB2 gene and a dinucleotide change replaced valine at position 221 with a termination codon (Fig. 1). The mutations c.172_175delTTGT, c.509_510delGA, and c.1240C>T belong to alterations that have already been described in the United States and different European countries (15, 17–19, 33, 36, 48), whereas seven other identified gene alterations are novel (Table 2).

An MLPA-based analysis identified three undescribed rearrangements within the PALB2 gene, two large deletions involving exons 7–8 and 9–10, respectively, and one duplication spanning exons 9–11 (Table 2). A deletion involving exons 7–8 (Fig. 2A) was detected in an HBC family (#1647) with two early-onset breast cancer cases. A specific junction fragment of 3347 bp was amplified from the patient’s DNA with a forward primer located in intron 5 and a reverse primer located in intron 9 (Supplementary Table S1). A sequence analysis of this fragment revealed a 3103 bp deletion (g.19557_22659del3103). The deletion breakpoints occurred in a region of perfect identity of 10 bp within two AluSx1 sequences located in intron 6 and 8. The deletion causes a shift in the reading frame and substantial truncation of the PALB2 protein (p.N863Gfs*7).

A deletion comprising exons 9–10 (Fig. 2B) was identified in an HBC family (#1507) with three cases of breast cancer. With PCR primers located in introns 7 and 11 (Supplementary Table S1), an extra fragment of 6779 bp was amplified from the patient’s DNA but not from control DNA. The sequencing of this PCR product demonstrated a deletion of 3424 bp and a substitution of C to G at position the g.26372 of intron 10 (g.22947_26370del3424, 26372C>G). Breakpoints were located in a sequence...
containing 16 identical nucleotides within AluSx3 and AluSx6 repeats in intron 8 and 10, respectively. Although the deletion of exons 9–10 maintains the PALB2 reading frame, an elimination of the gene region coding for 93 amino acids (p.A946_W1038del) that interfere with WD-40 domains essential for BRCA2 binding (residues 850–1186; ref. 49) may be considered pathogenic.

The duplication of the sequence containing exons 9–11 (Fig. 2C) was found in a patient (#79) who was affected by breast, ovarian, and colon cancer. With duplication-specific primers in introns 10 (forward) and 9 (reverse; Supplementary Table S1), a fragment of 4932 bp was amplified from the patient’s DNA but not from control DNA. A sequence analysis of this fragment revealed a duplicated region of 13686 bp (g.22904–36589dup) containing exons 9–11. Breakpoints were mapped to a 26-bp region of an identical sequence within two Alu elements, namely AluSx3 in intron 8 and AluY located in intron 11. The duplication of exons 9–11 results in an out-of-frame translation leading to the truncation of the PALB2 protein (p.G1068Gis=7).

Other detected sequence variants of the PALB2 gene including silent and missense substitutions have been previously reported as nonpathogenic (11); one novel substitution has been predicted as probably damaging and four have been assessed as tolerable (Supplementary Table S2).

Characteristics of PALB2 mutation carriers from HBC families

The mean age of breast cancer diagnosis in HBC families was lower in 13 PALB2 heterozygotes (44.3 years) than in 222 patients not carrying a mutation in the PALB2 gene (47.4 years), but the difference was not statistically significant (P = 0.12). However, it should be noted that the age at diagnosis in all high-risk families and therefore also in PALB2 mutation carriers is significantly lower from that in unselected patients with breast cancer (data not shown). Two cases of bilateral breast cancer (15.4%; 2 of 13) occurred in patients with a PALB2 mutation, whereas 14 bilateral cases (6.3%; 14 of 222) were registered in PALB2-negative patients (P = 0.22). An analysis of cancer profiles in 13 HBC families with PALB2 mutations (Table 2) revealed two cases of pancreatic cancer, whereas four cases of this cancer were reported in 222 families without a PALB2 mutation. Invasive ductal carcinomas predominated among PALB2-associated tumors; medullary carcinoma was reported in one carrier (#379). Five of nine PALB2-associated tumors were negative for the expression of estrogen and progesterone receptors and three of these also lacked the expression of a HER2 receptor (Table 2).

In five PALB2 families, we obtained DNA samples from other family members to assess the segregation of PALB2 mutations with the breast cancer phenotype. Segregation was demonstrated in four families (Fig. 3A–D), whereas in family #1120 the pedigree analysis did not show segregation of the recurrent mutation c.172_175delTTGT with the cancer phenotype (Fig. 3E).

Analysis of the recurrent PALB2 mutation c.172_175delTTGT in unselected breast cancer cases

The presence of the recurrent mutation c.172_175delTTGT was further analyzed in an independent group of 704 unselected patients with consecutive breast cancer and two other carriers (0.3%) were found (Table 2).

Haplotype analysis of c.172_175delTTGT mutation carriers

A haplotype analysis was performed on all six identified mutation carriers (four from high-risk patients and two from unselected breast cancer patients) and on 16 randomly selected samples from noncancer controls using three microsatellite markers flanking the PALB2 gene. Four of six unrelated carriers shared a common approximately 1.0 Mb haplotype defined by the D16S412, D16S417, and D16S420 markers, suggesting the unique origin of the c.172_175delTTGT mutation (Table 3). The detected disease-associated haplotype was not found in control DNA samples (data not shown) and also in two identified mutation carriers. Interestingly, one of them (#1120) comes from the previously mentioned family with a deficient segregation of the mutation with the disease.

Discussion

We have identified 16 pathogenic mutations in the whole series of 409 high-risk patients (3.9%) and 13 mutations in a group of 235 HBC families (5.5%). This frequency of PALB2 mutations is markedly higher than in other analyzed populations (15). The majority of truncating mutations was unique to individual families; seven of them have not yet been described. The only recurrent mutation found in 25% (4 of 16) of carriers was the c.172_175delTTGT. This alteration is not restricted to the Czech region but has also been detected in families of German and Irish ancestry (13, 15). Its frequency observed in a large population of unselected patients with breast cancer (0.3%) was lower compared with the frequency of the recurrent mutation c.1592delT reported by Erkko and colleagues from Finland (18 of 1,918; 0.9%; ref. 12).

We have identified large rearrangements at the PALB2 locus in three families, which represents 18.8% (3 of 16) of all detected mutations and suggests that this type of gene alteration may play a notable role in predisposition to breast cancer. An analysis of a larger group of patients is needed to obtain statistically relevant results. Alu sequences were involved in all detected rearrangements. To date, a large rearrangement in PALB2 was detected only in a breast cancer family in Spain (28) and in a Canadian patient affected with breast and pancreatic cancer (35).
mutation-positive families (Fig. 3A–E). Rahman and colleagues estimated initially that \( \textit{PALB2} \) mutations were associated with a 2.3-fold increased risk of breast cancer (11), but following studies have reported a higher risk (15, 25, 30, 50). A tight interaction between the \( \textit{PALB2} \) and \( \textit{BRCA2} \) proteins in DNA double-strand break repair (8, 9) indicates that also the disease phenotype and breast cancer penetrance may be similar in \( \textit{PALB2} \) and \( \textit{BRCA2} \) mutation carriers. This assumption support reports of Southey and colleagues (30) and Erkko and colleagues (50). The \( \textit{PALB2} \) c.3113G>A mutation identified by Southey and colleagues (30) in an Australian study was associated with 49% breast cancer risk by the age of 50 years and 91% risk [95% confidence interval (CI), 44%–100%] by the age of 70 years. The authors concluded that the HR of breast cancer for their recurrent \( \textit{PALB2} \) mutation was similar to the age-specific HRs reported for mutations in the \( \textit{BRCA2} \) gene. Erkko and colleagues (50) estimated that the recurrent Finnish c.1592delT mutation is associated with a 40% (95% CI, 17%–77%) risk of breast cancer to the age of 70 years.

Similar to \( \textit{BRCA2} \), defects in the \( \textit{PALB2} \) gene are also associated with hereditary predisposition to male breast cancer (15, 31) and pancreatic cancer (33–35) and according to some results they may also predispose to ovarian cancer (18, 36). A comparison of cancer profiles in mutation-positive and -negative families in our study indicated only a weak association of \( \textit{PALB2} \) mutations with pancreatic and ovarian cancer. Further information from a larger population of \( \textit{PALB2} \) families will be necessary for a more precise evaluation of these data.

One \( \textit{PALB2} \) mutation was detected in a small group of

22 male breast cancer cases, which may support the view of breast cancer predisposition in men with mutations in **PALB2**.

A negative steroid receptor status predominated in breast tumors (reported in 5 of 9 tumors) from heterozygous mutation carriers (Table 2). Receptor negativity has also been observed in some other studies (23, 27). In contrast, the positivity of steroid receptors in most **PALB2**-positive tumors has been reported by other groups (12, 16).

Pathogenic mutations of the **BRCA1** and **BRCA2** genes detected in our patients with high-risk breast/ovarian cancer were more frequent than mutations identified in the **PALB2** gene (Supplementary Table S3). However, protein truncating mutations in **PALB2** strongly prevailed over alterations in other candidate breast cancer–susceptibility genes (ATM, CHEK2, and NBN) we examined in **BRCA1**- and **BRCA2**-negative patients (3, 4, 6). In familial cases, mutations in **PALB2** were found exclusively in a subgroup of HBC families with a frequency comparable with that previously reported for mutations in **BRCA2** (Table 1 and Supplementary Table S3).

The presented results thus suggest that screening for protein-truncating alterations and LGRs at the **PALB2** locus is relevant at least in HBC families and support the recently published suggestions that screening for **PALB2** mutations may be clinically useful (15, 37) in addition to recently published suggestions that screening for **PALB2** gene (51). Further analyses of a larger series of patients are highly desirable for accurate estimation of breast cancer penetrance to improve clinical management in **PALB2** mutation carriers, and to reveal whether genetic testing for the **PALB2** gene may also be recommended to other risk groups, including, for example, male breast cancer cases.

**Disclosure of Potential Conflicts of Interest**

No potential conflicts of interest were disclosed.

**Authors' Contributions**

Conception and design: M. Janatova, Z. Kleibl, P. Pohlreich

Development of methodology: M. Janatova, Z. Kleibl, P. Pohlreich

Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): A. Panczak, K. Vesela, M. Zimovjanova, P. Dundr

Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): M. Janatova, J. Stribrna, P. Kleiblova, J. Soukupova

Writing, review, and/or revision of the manuscript: M. Janatova, Z. Kleibl, J. Stribrna, A. Panczak, K. Vesela, P. Kleiblova, J. Soukupova, P. Pohlreich

Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): M. Janatova, A. Panczak, K. Vesela, P. Dundr

Study supervision: P. Pohlreich

**Acknowledgments**

The authors thank Stanislav Kormunda for help with statistical analyses, Marie Epsteinova and Marketa Dostalova for their excellent technical assistance, and all patients for cooperation in this project.

**Grant Support**

This study was supported by Internal Grant Agency of the Ministry of Health of the Czech Republic number NT13343 (to M. Janatova, Z. Kleibl, J. Stribrna, A. Panczak, K. Vesela, M. Zimovjanova, P. Kleiblova, J. Soukupova, and P. Pohlreich) and number NT14006 (to M. Janatova, Z. Kleibl, P. Kleiblova, and P. Pohlreich), and Charles University in Prague project PRVOUK-P27/LFJ1/1 (to M. Janatova, Z. Kleibl, A. Panczak, P. Dundr, and P. Pohlreich).
