The Effects of Aerobic Exercise on Estrogen Metabolism in Healthy Premenopausal Women

Alma J. Smith1, William R. Phipps2, William Thomas3, Kathryn H. Schmitz4, and Mindy S. Kurzer1

Abstract

Background: It is well accepted that exercise can decrease breast cancer risk. Limited clinical evidence suggests that this risk could be mediated through changes in estrogen metabolism in premenopausal women. Our objective was to investigate the effects of exercise on premenopausal estrogen metabolism pertinent to breast cancer risk.

Methods: Sedentary, healthy, young eumenorrheic women were randomized into an intervention of 30 minutes of moderate-to-vigorous aerobic exercise five times a week for approximately 16 weeks (n = 212), or into a usual-lifestyle sedentary control group (n = 179). Urinary levels of estrogens [estrone (E1), estradiol, and estriol] and nine estrogen metabolites were measured at baseline and at study end by liquid chromatography/tandem mass spectrometry. The ratios of 2-hydroxyestrone to 16a-hydroxyestrone (2-OHE1/16α-OHE1) and 2-OHE2 to 4-hydroxyestrone (2-OHE1/4-OHE1) were also calculated.

Results: The exercise intervention resulted in significant increases in aerobic fitness and lean body mass and a significant decrease in percent body fat. For exercisers who completed the study (n = 165), 2-OHE1/16α-OHE1 increased significantly (P = 0.043), whereas E1 decreased significantly (P = 0.030) in control participants (n = 153). The change from baseline in 2-OHE1/16α-OHE1 was significantly different between groups (P = 0.045), even after adjustment for baseline values.

Conclusions: The exercise intervention resulted in a significant increase in the 2-OHE1/16α-OHE1 ratio but no differences in other estrogen metabolites or ratios.

Impact: Our results suggest that changes in premenopausal estrogen metabolism may be a mechanism by which increased physical activity lowers breast cancer risk. Cancer Epidemiol Biomarkers Prev; 22(5): 756–64. © 2013 AACR.

Introduction

It is well-accepted that lifetime estrogen exposure increases the risk for breast cancer as a result of cumulative stimulation of epithelial cell division by estrogen (1). It has also been suggested that some metabolites resulting from the biotransformation and inactivation of estrogen can play a significant role in breast carcinogenesis (2). Specifically, the products resulting from the oxidation of estradiol (E2) and estrone (E1) known as hydroxysterogens have been shown to display varying degrees of carcinogenicity. For example, 2-hydroxyestrone (2-OHE1) partially antagonizes the growth-stimulatory effect of E2 in cultured human MCF-7 breast cancer cells (3) whereas 2-hydroxyestradiol (2-OHE2) has little or no carcinogenic activity in Syrian hamsters (4, 5). In cultured mouse mammary epithelial cells, 16α-hydroxyestrone (16α-OHE1) increases unscheduled DNA synthesis and promoted anchorage-independent growth (6, 7). The metabolite 4-hydroxyestrone (4-OHE1) is considered genotoxic due to its redox cycling process, which generates reactive oxygen species (ROS) and highly cytotoxic semiquinone/quinone intermediates that react with DNA (2). The 2-hydroxyestrone also undergo redox cycling but appear to lack carcinogenic activity due to a more rapid clearance in vivo (8) associated with a faster rate of inactivation through O-methylation (9, 10). Finally, one product resulting from O-methylation, namely 2-methoxyestradiol (2-MeOE2), has been shown to be a potent inhibitor of cell proliferation and angiogenesis (11, 12).

Despite evidence suggesting the possible importance of other aspects of estrogen metabolism on breast cancer, human studies have largely focused on the ratio of 2-OHE1 to 16α-OHE1 (2-OHE1/16α-OHE1). Given the different genotoxic capacity of these metabolites, it has been hypothesized that metabolism favoring the production of 2-OHE1 over 16α-OHE1 may be inversely associated with...
breast cancer risk (13). In premenopausal women, the strongest evidence in favor of this hypothesis comes from 2 early prospective studies in which urine specimens were collected several years before diagnosis. In the Guernsey III cohort study, women in the highest tertile of urinary 2-OHE1/16α-OHE1 ratio had a nonsignificantly lower OR (0.75) for breast cancer than women in the lowest 2 tertiles (14). Similarly, in a study reported by Muti and colleagues, women in the highest quintile of the urinary 2-OHE1/16α-OHE1 ratio had an adjusted OR for breast cancer of 0.58, although again this was not statistically significant (15). In contrast, in a more recent prospective study, a higher 2-OHE1/16α-OHE1 ratio was associated with an increase in premenopausal estrogen receptor (ER)-positive breast cancer (16). However, the association was not statistically significant and estrogen metabolites were measured in serum and not in urine as in the 2 previous studies. Significant relationships between premenopausal breast cancer risk and urinary levels of estrogen metabolites and their ratios have been observed in some case–control studies, but findings have been inconsistent. The case–control studies of both Coker and colleagues (17) and Kabat and colleagues (18) found an increased risk in women with an increased 2-OHE1/16α-OHE1 ratio, but other studies did not (19–21). As for other measures, in 2 other studies, control women had significantly higher levels of 2-hydroxysterogens, 4-hydroxysterogens, 16α-OHE1 (22), and 2-OHE1/4-OHE1 ratio (23) than women with breast cancer. While the association between estrogen metabolism and breast cancer risk needs further investigation, epidemiologic evidence strongly supports the association between higher levels of aerobic exercise and reduced risk for breast cancer (24). However, whether exercise in premenopausal women results in what may be favorable effects on estrogen metabolism is not clear. For example, in one small study, highly fit women exercising strenuously for 368 min/wk had similar values of 2-OHE1, 16α-OHE1, and 2-OHE1/16α-OHE1 ratio than those of women exercising recreationally for only 60 min/wk (25). In contrast, in another small study, higher levels of self-reported physical activity were associated with higher urinary concentrations of 2-OHE1 and a higher 2-OHE1/16α-OHE1 ratio (26). Recently, a large study of 603 women from the Nurses’ Health Study II found high levels of physical activity not only to be correlated with a higher 2-OHE1/16α-OHE1 ratio but also significantly lower levels of E2 and 16α-OHE1 (27). In comparison, data from exercise intervention studies have been conflicting. For instance, in interventions lasting 12 weeks (28), 16 weeks (29), or even 6 months (30), moderate-to-vigorous intensity aerobic exercise in premenopausal women did not result in any significant changes in urinary concentrations of E2, E2 estriol (E3), 2-hydroxysterogens, 4-hydroxysterogens, 16α-OHE1, or either 2-OHE1/16α-OHE1 or 2-OHE1/4-OHE1 ratios. In 2 small exercise interventions coupled with calorie restriction lasting 4 and 6 months, there were significant increases in urinary levels of luteal phase 16α-OHE1 and 2-OHE1/16α-OHE1, respectively (31, 32).

Overall, the data on the effects of aerobic exercise on premenopausal estrogen metabolism are not only conflicting but also narrow in scope. With the exception of 2 studies (27, 29), all published studies to date have focused on a limited number of estrogen metabolites, namely, 2-OHE1 and 16α-OHE1, and their ratio. Furthermore, no study has yet investigated the levels of the 2- and 4-methylated catecholestrogens despite their purported role in breast carcinogenesis as suggested by culture and animal studies. The WISER (Women In Steady Exercise Research) study was a large, randomized, exercise-controlled, parallel-arm, clinical study investigating the effects of 16 weeks of moderate-to-vigorous intensity aerobic exercise on several parameters pertinent to breast cancer risk in sedentary, healthy, young eumenorrheic women. Here, we report changes from baseline in urinary levels of estrogens (E1, E2, and E3), 9 estrogen metabolites [2-OHE1, 2-OHE2, 16α-OHE1, 4-OHE1, 4-hydroxyestradiol [4-OHE2], 2-methoxyestrone, 2-MeOE1, 2-MeOE2, 4-methoxyestrone [4-MeOE1], and 4-methoxyestradiol [4-MeOE2]], and 2 estrogen metabolite ratios (2-OHE1/16α-OHE1 and 2-OHE1/4-OHE1).

Materials and Methods

Study design

The WISER study was a randomized clinical trial investigating the effects of a 16-week aerobic exercise intervention on breast cancer biomarkers of healthy, premenopausal women. All procedures were approved by the Human Subjects Review Committee at the University of Minnesota (Minneapolis, MN; Institutional Review Board; IRB ID#0505M69867). Written informed consent was obtained from each participant before participation. A complete description of the study design including participant recruitment, screening, randomization, and retention has been published (33).

Briefly, WISER study investigators emailed more than 100,000 female residents of the Minneapolis–St. Paul metropolitan area regarding participation. Women who were interested were screened online based on age (18–30 years old), physical activity (2 or less weekly sessions of moderate intensity exercise), smoking status (nonsmoking), body mass index (BMI; 18–40 kg/m² inclusive), and self-reported menstrual cycle length (24–35 days). Women who met these criteria were further screened via telephone (n = 1684) and excluded on the basis of previous hormonal contraception use (past 3 months or 12 months if depot-medroxyprogesterone acetate), gynecologic problems, metabolic or endocrine-related diseases, current or recent (past 6 months) pregnancy, nonmelanoma cancer in the past 5 years, alcohol consumption (more than 7 servings/wk), and body weight changes (more than 10% over the past year).

Of the 966 women who attended a 2-hour orientation, 391 provided written consent and were enrolled in the study. After baseline measurements, women were
randomized into either an exercise intervention (n = 212) or a no-exercise, usual-lifestyle control group (n = 179) for approximately 16 weeks. Randomization was stratified on baseline BMI tertiles (≤22.8, 22.8–26.3, ≥26.3) based on the 50th and 75th percentiles from NHANES I data and age (18–24 vs. 25–30). Participants who failed to return for follow-up measures were dropped from the study. In addition, exercisers were subject to study exclusion if they missed 15 or more exercise sessions. Figure 1 shows the recruitment, screening, randomization, retention, and completion of WISER participants.

Exercise intervention

Women randomized to the exercise intervention trained aerobically 5 times a week for 30 minutes on a treadmill, stair-stepper, or elliptical machine, at a specified intensity based on age-predicted maximal heart rate (max HR) for 16 weeks (±2 weeks). The exercise intensity was initially set at 65% to 70% of the age-predicted max HR and was gradually increased by 5% every 4 weeks until 80%–85% of age-predicted max HR was reached (stage 1 = 65%–70%; stage 2 = 70%–75%; stage 3 = 75%–80%; stage 4 = 80%–85%).

All training sessions took place at the University of Minnesota’s Recreation Center. At the first training session, a certified personal trainer provided instruction on the proper use of the exercise machines, heart rate monitor and watch, and completion of an exercise log after each workout. Trainers supervised exercise sessions and reviewed the exercise logs at least once weekly to monitor adherence and safety. When not meeting with a trainer, participants were expected to complete the remaining of the workout sessions unsupervised. Exercise adherence was assessed using the data from the heart rate monitor (Polar Electro Inc.) and exercise logs.

Any physical activity conducted after randomization and outside the prescribed exercise intervention was assessed at the end of the study with a physical activity questionnaire administered by a research staff member. All participants, regardless of randomization outcome, were asked to maintain their baseline body weight. Control participants were asked to not only maintain their usual level of physical activity but also to not change their eating habits.

Anthropometrics

Body mass was measured to the nearest 0.1 kg using an electronic scale (Scale Tronix) 4 times throughout the study (baseline, intervention weeks 4 and 8, and follow-up). Height was measured without shoes to the nearest 0.1 cm (Scale Tronix) by a stadiometer at baseline. BMI was calculated by dividing body mass in kg by height in meters squared (kg/m²). Body composition was
assessed at baseline and follow-up by dual-energy X-ray absorptiometry (DXA) using a Lunar Prodigy DXA apparatus (Lunar Radiation Corp.).

**Aerobic fitness and physical activity**

Aerobic fitness was assessed at baseline and immediately after the intervention with a submaximal treadmill test described previously (33). This workload was then converted to metabolic equivalents (MET) by using a standard conversion formula (34). Self-reported physical activity conducted a year before the study and during the 4-month follow-up period was assessed by a research staff using a modified version of the Modifiable Activity Questionnaire (35). This information was transformed into MET-hours per week (MET-h/wk) using commonly accepted MET values (36).

**Dietary intake**

Usual dietary intake was assessed through self-reported, 3-day food records completed concomitantly with the urine collections at baseline and follow-up. Nutrient intake was determined using The Food Processor SQL by ESHA Research.

**Urine collection**

Forty-eight hours before the urine collection, participants were asked to avoid moderate or vigorous exercise and abstain from alcohol. Urine was collected for 3 consecutive 24-hour periods in the midfollicular phase (follicular days 7–9 of baseline menstrual cycle 2 and consecutive 24-hour periods in the midfollicular cycle 6). Throughout each day, urine was collected in a 1-L bottle and kept cold with ice packs inside an insulated bag. At the end of each collection day, urine was transferred into a 3-L bottle containing ascorbic acid (1 mg/mL) to prevent oxidation and stored in a home refrigerator or cooler provided by the study. Once the urine collection was completed, collection bottles were retrieved by a research staff member and brought to the General Clinical Research Center at the University of Minnesota for processing. Urine was refrigerated and urine samples with nondetectable levels were assigned values of the lowest detectable standard (0.014 ng/mL urine). Concentrations were expressed both as nanomol per day (nmol/d) and nanograms per milligram of creatinine (ng/mg Cr). Urinary creatinine was analyzed at the Fairview University Diagnostic Laboratories.

Samples were run in duplicate and in batches such that each batch contained both baseline and follow-up samples from each participant and an equal number of exercise and control participants. One quality control sample was included in each batch. The mean intra- and interassay coefficient of variations (CV) were 5.1% and 13.4% for E₁; 5.2% and 16.0% for E₂; 5.6% and 11.4% for E₃; 4.2% and 12.3% for 2-OHE₁; 7.7% and 10.8% for 2-OHE₂; 6.2% and 18.7% for 16α-OHE₁; 4.3% and 12.2% for 4-OHE₁; 14.0% and 51.2% for 4-OHE₂; 7.0% and 11.3% for 2-MeOE₁; 5.8% and 10.0% for 2-MeOE₂; 7.4% and 10.3% for 4-MeOE₁; and 6.9% and 7.9% for 4-MeOE₂.

**Statistical analyses**

Unadjusted comparisons of baseline characteristics were conducted using Student t tests for continuous variables and χ² tests for categorical variables. Two estrogen metabolite ratios of interest, namely, the 2-OHE₁/16α-OHE₁ ratio and 2-OHE₁/4-OHE₁ ratio, were calculated by dividing the concentration of 2-OHE₁ by either 16α-OHE₁ or 4-OHE₁, respectively.

**Results**

Of the 212 and 179 women randomized into the exercise and control groups, 165 (77.8%) and 153 (85.5%), respectively, completed the WISER study. With the exception of education (47% of dropouts had some college education vs. 27% of study completers, P = 0.002), dropouts were no different from women who completed the study in any of the baseline demographic characteristic measured (data...
Also, there were no significant differences between exercisers and controls in baseline demographic characteristics (Table 1). In general, women who completed the study were mostly Caucasian (72%), single (82%), nulliparous (93%), had education beyond high school (96%), and had no first-degree relatives with breast cancer (97%).

Baseline estrogen metabolism
With the exception of 2-OHE1 ($P = 0.084$) and 2-OHE1/16α-OHE1 ratio ($P = 0.044$), exercisers had similar levels of urinary estrogens, estrogen metabolites, and 2-OHE1/4-OHE1 ratio than control participants at baseline (Table 2). No significant baseline associations between any of the urinary endpoints and measures of body composition, adiposity, fitness, reproductive characteristics, and diet were found.

Overall, the concentration of estrone and its metabolites were higher than their estradiol counterparts, especially for E1, 2-OHE1, 4-OHE1, and 4-MeOE1 as compared with E2, 2-OHE2, 4-OHE2, and 4-MeOE2, respectively. Estrogen hydroxylation showed an isomeric preference for the C-2 position. Specifically, concentrations of 2-OHE1 were about 14- and 20-fold higher than those of 16α-OHE1 and 4-OHE1, respectively, and concentration of 2-OHE2 about 40-fold those of 4-OHE2.

Exercise adherence
On average, exercise participants completed 127 min/wk of the assigned 150 minutes of exercise intervention. Details about exercise adherence and compliance can be found elsewhere (38).

Intervention effects
The exercise intervention resulted in significant improvements in body composition and aerobic fitness without changes in body weight. As previously reported, exercisers experienced significant increases in aerobic fitness (0.90 METs reached at 85% of max HR vs. 0.12 METs in controls) and lean body mass (0.55 vs. 0.07 kg), as well as significant decreases in fat mass (0.57 vs. 0.04 kg) and percent body fat (0.95% vs. 0.09%). In contrast, control participants experienced no changes in body composition, aerobic fitness, and body weight despite a significant reduction in daily caloric intake (−224 kcal/d). Exercisers also reduced their food consumption, but only by 18 kcal/d ($P > 0.05$). Details on the effects of this intervention on body composition, aerobic fitness, and energy intake have been published previously (39).

As previously reported, the exercise intervention resulted in no significant changes in endogenous levels of E2, estrone sulfate, progesterone, T, or SHBG (38). Exercisers, however, did experience a significant increase in

NOTE: There were no significant differences at baseline between study groups for any of these variables.

$a_n = 310.$

$b_n = 251.$

$c_n = 312.$
urinary 2-OHE1/16α-OHE1 ratio (P = 0.043), whereas controls had a nonsignificant decrease in 2-OHE1/16α-OHE1 ratio. The difference in the change from baseline in 2-OHE1/16α-OHE1 ratio between groups was significant (P = 0.045), even after adjustment for baseline values.

Figure 2 shows that many, but not all, of the participants who experienced an absolute change in 2-OHE1/16α-OHE1 ratio greater than 100 had a high baseline
2-OHE₁/16α-OHE₁ ratio. Levels of E₁ remained unchanged in exercisers but decreased in controls resulting in a statistically significant change from baseline between the groups (P = 0.042). No significant within-group changes or between-group differences at follow-up were observed for other estrogens, estrogen metabolites, or ratios.

Discussion

We found that in healthy premenopausal women, an exercise regimen of 150 minutes of moderate-to-vigorous aerobic exercise per week for 16 weeks resulted in significant changes in estrogen metabolism in a direction consistent with reduction of breast cancer risk. Specifically, exercise participants experienced a significant increase in urinary levels of 2-OHE₁ and a small nonsignificant decrease in 16α-OHE₁ levels. These changes resulted in a significant increase in the 2-OHE₁/16α-OHE₁ ratio. In contrast, women in the control group had a nonsignificant decrease in 2-OHE₁/16α-OHE₁ ratio largely attributable to those few controls with large baseline ratio having large decreases in the ratio. Controls also had an unexplained significant decrease in E₁. We did not find evidence for exercise resulting in changes in the 4-hydroxylation pathway or other differences that conceivably could have been found.

Overall, our results differ from those of other exercise intervention studies investigating the effects of aerobic exercise on premenopausal estrogen metabolism. For instance, in a small 5-month weight loss clinical trial involving moderate-intensity exercise, both controls and exercisers had significant increases in urinary 2-OHE₁/16α-OHE₁ ratio, but in contrast to our results, the change in ratio between the groups was not statistically significant (32). In a small pre-post design study, 4 months of moderate exercise coupled with calorie restriction resulted in nonsignificantly higher urinary levels of 2-OHE₁ and 16α-OHE₁ and the ratio (31). In our study, both 2-OHE₁ and the 2-OHE₁/16α-OHE₁ ratio increased significantly whereas 16α-OHE₁ decreased nonsignificantly. Both of these studies differed from our study in that aerobic exercise was coupled with significant calorie restriction making it impossible to discern whether the changes reported were the result of the exercise or diet. When compared with exercise-only interventions, our study remains the only one to report significant changes in estrogen metabolism. For example, in a moderate-to-vigorous aerobic exercise intervention lasting 12 weeks (30–45 minutes, 4 d/wk), Campbell and colleagues reported no significant changes in urinary premenopausal levels of 2-OHE₁, 16α-OHE₁, or 2-OHE₁/16α-OHE₁ ratio (28). Similarly, in a pilot study conducted by our research group, total levels of 2-OHE (2-OHE₁ + 2-OHE₂), 4-OHE (4-OHE₁ + 4-OHE₂), and the 2-OHE₁/16α-OHE₁ ratio remained unchanged in 15 young women exercising aerobically for 30 min/d, 5 times a week for 16 weeks (29). Similarly, Robles-Gil and colleagues did not find significant changes in E₁, E₂, or E₃ in 20 premenopausal women after 6 months of 60 minutes of moderate-intensity exercise 3 d/wk (30).

A possible explanation for the disparity between the results reported by these exercise intervention studies, and our study may be found in the choice of study design and methodology. The WISER study had many methodologic advantages over previously published research. First, the sample size in our study (n = 318) was an order of magnitude or more large than those of the other three studies. Second, our study design used randomized controls (only Campbell and colleagues study was randomized). Third, unlike the studies of Campbell and colleagues and Robles-Gil and colleagues, in which first morning urine samples were used, WISER participants collected three 24-hour urine collections allowing for a more robust and representative analysis of the chronic
effect of aerobic exercise on estrogen metabolism. Finally, our study provides the most comprehensive analysis on the effects of exercise on estrogen metabolism to date. We have analyzed urinary levels of the major parent estrogens (E1, E2, and E3) and 9 of their estrogen metabolites by LC/MS-MS. This newer methodology is considered to be superior not only to the ELISA methods used by these studies but also to the current gold standard gas chromatography/mass spectroscopy (GC/MS) due to its increased sensitivity and sample throughput (37, 40). Unlike Xu and colleagues, we were able to quantify and report 4-OHE2, concentrations, although its lack of detection in 53.4% of our samples resulted in a higher-than-expected interassay CV.

Altogether, the findings of the WISER study are significant because they provide the first clinical evidence that aerobic exercise can significantly change estrogen metabolism in premenopausal women. Specifically, our results show that such an exercise intervention can lead to increases in 2-OHE1 and possible decreases in 16α-OHE1 ultimately resulting in significant increases in the 2-OHE1/16α-OHE1 ratio. Importantly, increases in this ratio have been associated with a significant reduction in breast cancer risk. From a clinical point of view, the assessment of urinary 2-OHE1/16α-OHE1 ratio is also relevant as it has been found to be a good approximation of the 2-OHE1/16α-OHE1 ratio of breast tissue (41). Perhaps one mechanism by which exercise mediates estrogen metabolism is through the regulation of P450 cytochrome enzymes responsible for controlling estrogen hydroxylation and catecholestrogen methylation. Given the implication these results have for breast cancer prevention efforts, future studies should not only attempt to corroborate our results but also investigate the exact mechanisms by which exercise leads to these favorable estrogen metabolism changes.

The Effects of Aerobic Exercise on Estrogen Metabolism in Healthy Premenopausal Women
