Long-Term Physical Activity Trends in Breast Cancer Survivors

Caitlin Mason, Catherine M. Alfano, Ashley Wilder Smith, Ching-Yun Wang, Marian L. Neuhouser, Catherine Duggan, Leslie Bernstein, Kathy B. Baumgartner, Richard N. Baumgartner, Rachel Ballard-Barbash, and Anne McTiernan

Abstract

Background: Physical activity is associated with reduced mortality and higher quality of life in breast cancer survivors; however, limited data on the prevalence of activity and long-term trends after diagnosis are available.

Methods: A multiethnic cohort of 631 women (18–64 years) with stage 0 to IIIA breast cancer was followed for 10 years. Recreational aerobic activity (MET-h/wk) was ascertained for the year before diagnosis (baseline), 24 months, 5 years, and 10 years after enrollment. Women were classified according to U.S. physical activity guidelines (>150 min/wk moderate or >75 min/wk vigorous activity). The OR for meeting guidelines at 5 and 10 years according to baseline factors was estimated using logistic regression. The change in MET-h/wk was predicted using linear regression.

Results: Prediagnosis, 34% of women met physical activity guidelines; 34.0%, 39.5%, and 21.4% met guidelines at 24 months, 5 years, and 10 years after enrollment, respectively. Less than 8% of survivors met guidelines at all follow-up periods. Over 10 years, recreational aerobic activity decreased by a mean ± SD of 4.3 ± 16.2 MET-h/wk. Meeting guidelines pre-diagnosis was strongly associated with meeting guidelines at 5 years [OR (95% confidence interval; CI): 2.76 (1.85–4.1)] and 10 years [OR (95% CI): 3.35 (2.13–5.28)]. No other demographic or prognostic factors were significantly associated with the 10-year change in MET-h/wk.

Conclusion: The vast majority of early breast cancer survivors do not meet national exercise recommendations 10 years postdiagnosis.

Impact: Physical activity levels are low in breast cancer survivors across the 10 years postdiagnosis; nonetheless, the predictors of activity in this population remain poorly understood.

Introduction

With 2.9 million female breast cancer survivors living in the United States and another 80,000 added each year (1), there is considerable interest in factors that promote the long-term health and well-being of these women. Available evidence supports a positive effect of postdiagnosis exercise participation on quality of life, fatigue, and body image (2), as well as the prevention, attenuation, or reversal of other persistent adverse treatment effects including pain, depression, and weight gain (3, 4). Regular physical activity is associated with reduced all-cause mortality (5) as well as extended survival from breast cancer (5, 6, 7–9), even among women who were inactive prior to diagnosis (5, 8). Because a significant number of all metastases and recurrences occur more than 5 years after the initial diagnosis (i.e., overall cumulative incidence of developing distant metastases is 20% at 4 years, 30% at 8 years, and 36% at 12 years; refs. 10–14), physical activity may be a modifiable factor to improve the prognosis and quality of life of long-term survivors.

A previously published report describing physical activity levels among breast cancer survivors in the Health, Eating, Activity and Lifestyle (HEAL) study up to 30 months postdiagnosis indicated that, on average, participants decreased their total activity by approximately 2 hours per week from prediagnosis to postdiagnosis (15). In a recent analysis from the Women’s Health Initiative Observational Study and clinical trials, postdiagnosis physical activity levels decreased among 25% of women with breast cancer and were unchanged in 35%
over a maximum of 6 years of follow-up (5). Age-related declines in physical activity are well documented (16, 17); however, the degree to which a breast cancer diagnosis affects long-term physical activity participation has not been well characterized, in part, because of the difficulty in maintaining a cohort of survivors over an extended period of time.

Identifying opportunities for physical activity promotion by characterizing physical activity participation after breast cancer diagnosis and treatment is important given that breast cancer survivors represent a large and growing population of women (18) for whom postdiagnosis modifiable lifestyle factors are of particular interest. Accordingly, the purpose of this report is to describe the level of physical activity participation in a multiethnic cohort of breast cancer survivors who were followed for 10 years after their initial postdiagnosis assessment.

Materials and Methods

Setting, patients, and recruitment

The HEAL study is a multiethnic prospective cohort study that enrolled 1,183 women with a first primary breast cancer (Stage 0–IIIA) from Surveillance, Epidemiology and End Results (SEER) registries in New Mexico, Los Angeles County, California, and Western Washington. The purpose of the HEAL study is to determine whether lifestyle, hormones, and other exposures affect breast cancer prognosis (8, 19, 20). The study design, procedures, and data collection methods have been previously described in detail (20, 21). Briefly, in New Mexico, 615 women (≥18 years) diagnosed between July 1996 and March 1999, and living in Bernalillo, Santa Fe, Sandoval, Valencia, or Taos counties were recruited. In Western Washington, 202 women (age range: 40–64 years) diagnosed between September 1997 and September 1998, and living in King, Pierce, or Snohomish counties were recruited. In Los Angeles County, 366 African American women (age range: 35–64 years) diagnosed between May 1995 and May 1998 who had participated in the Los Angeles portion of the Women’s Contraceptive and Reproductive Experiences (CARE) Study or in a parallel case-control study of in situ breast cancer were added to the HEAL cohort.

All study protocols were approved by the Institutional Review Boards of each participating center, in accordance with an assurance filed with and approved by the U.S. Department of Health and Human Services. Written informed consent was obtained from each participant. Women completed an interview approximately 6 months after diagnosis (baseline), and were contacted for follow-up assessments at 24 months, 5 years, and 10 years after enrollment. At the 10-year follow-up, 631 women completed a physical activity assessment and are included in this analysis (New Mexico: n = 315; Western Washington: n = 202; and Los Angeles County: n = 366). Of these, 631 and 606 reported physical activity at 24 months and 5 years, respectively. One woman had incomplete physical activity data at baseline and is, therefore, excluded from some analyses.

Data collection

Physical activity. At the Western Washington and New Mexico sites, physical activity data were collected using an interview-administered questionnaire developed on the basis of the validated Modifiable Activity Questionnaire (MAQ; ref. 22). The type, duration, and frequency of sports/recreational and household activities carried out in the past year were assessed. At the Los Angeles County site, a lifetime history of physical activity was obtained at baseline by asking respondents to recall any/all activities carried out for at least 1 h/wk. The ages at which the activity was done and the number of years the activity was done were recorded, as well as the average number of hours per week during the period of activity. All follow-up assessments (i.e., at 24 months, 5 years, and 10 years) were standardized across sites, again on the basis of the MAQ, and subjects were asked specifically about physical activities during the year prior to the interview.

Given the reported association between recreational aerobic activity and breast cancer prognosis in the literature (5, 6, 7–9), we chose to focus our analysis on this type of activity. Sixteen recreational physical activities (fast walking, jogging, running, hiking, aerobics, bicycling, swimming, tennis, golf, skiing, nordic track, fast dancing, bowling, rowing, horseback riding, and light calisthenics) were consistently assessed across all timepoints and were coded into composite variables for analysis: (i) a continuous variable of MET-h/wk of moderate to vigorous sports/recreational aerobic activity; and (ii) a 3-level categorical variable representing activity sufficient to meet current physical activity guidelines for all adults (≥150 min/wk moderate activity or ≥75 min/wk vigorous activity or an equivalent combination) in the United States (23), which was coded as no activity, activity not sufficient to meet guidelines, or meeting guidelines; 150 min/wk of moderate activity is equivalent to approximately 9 MET-h/wk.

For participants from the Western Washington and New Mexico sites, weekly average energy expenditure was computed from reported recreational aerobic activities by assigning MET values for each activity using the revised Compendium of Physical Activities (24). A MET is defined as the ratio of associated metabolic rate for a specific activity divided by resting metabolic rate (3.5 mL of O2 per kg of body weight) such that a 2-MET activity requires 2 times the resting metabolic energy expenditure as sitting quietly. Each reported activity was categorized as light (<3 METs), moderate (3–6 METs), or vigorous (>6 METs) intensity. Because participants from the Los Angeles County site were added to the HEAL cohort after baseline data collection, total aerobic activity in the year prior to diagnosis was constructed from the lifetime history measure of physical activity that provided METs for each year prior to diagnosis. Follow-up physical
activity was ascertained as for the other 2 sites. At each
timepoint, reported activities were converted to MET-h/wk.
A physical activity guideline variable, as described above, was derived in a manner compatible with data
from the other 2 sites.

**Covariates.** Demographic information, including standard measures of age, education, and race/ethnicity (African American, Hispanic, or non-Hispanic White), was collected at baseline, as was information on personal and family medical history, smoking, and age at meno-
pause. Measured height and weight at study enrollment
were used to compute body mass index (BMI) as weight
(kg)/height (m)² for participants from Washington and New Mexico. Disease stage was based on the American
Joint Committee on Cancer (AJCC) stage of disease clas-
sification obtained from the Surveillance, Epidemiology
and End Results (SEER) registry records. Breast cancer
treatment data were obtained from medical record
abstraction and SEER data and were coded as: surgery
only; surgery with radiation, or any chemotherapy. Use of
tamoxifen was obtained from medical record abstraction
and self-reported use at the baseline and 24-month assess-
ments; tamoxifen users were defined as women who used
tamoxifen at any time through to the 24-month follow-up
period. Menopausal status at baseline was determined
using an algorithm (25) that assigned women into pre-,
post-, or unclassifiable menopausal status on the basis of
age, date of last menstruation, hysterectomy and oopho-
rectomy status, and levels of serum estradiol, estrone, and
doillic-stimulating hormone. Comorbid medical condi-
tions were assessed at the 24-month interview by asking
participants to report which of 18 medical conditions plus
other cancers had ever been diagnosed by a physician, and
whether their current activities were limited by any of
these conditions. A comorbidity summary score was
generated on the basis of the number of medical condi-
tions that limited current activities, categorized as either 0
or 1 or more conditions.

Information on a limited number of covariates was
reassessed via self-reported questionnaire at the 5-year
and 10-year follow-ups. Changes in marital status,
employment, smoking status, and BMI over the 10-year
follow-period were, therefore, also considered as predic-
tors of the 10-year change in MET-h/wk. The change in
BMI was modeled as a continuous variable. Changes in
marital status, employment and smoking status were initially modeled as dichotomous variables (Y/N). Sub-
sequently, the following specific changes were also exam-
ined: (i) married or living with partner to other (widowed,
divorced, separated); (ii) employed to not employed
(including retirement, disability, or other leave); and (iii)
current smoker to former smoker.

**Statistical analysis**

Participant characteristics according to physical activity
(0, >0 to 9, or ≥9 MET-h/wk) in the year prior to diagnosis
were compared using analysis of variance and chi² tests as
appropriate. The baseline characteristics of women fol-
lowed through 10 years and those with missing data were
also compared. Linear regression was used to describe the
associations between baseline demographic and prognos-
tic factors and physical activity levels (MET-h/wk) at each
follow-up, as well as at the 10-year change in MET-h/wk.
The ORs for meeting physical activity guidelines at 5 and
10 years after diagnosis were calculated using logistic
regression, with and without adjustment for age and BMI
as continuous variables. The ORs for increasing (sufficient
to meet physical activity guidelines) or decreasing activity
over time were similarly calculated according to baseline
demographic and prognostic factors. A variety of predic-
tor variables were considered, including: age (<35 vs. ≥55
years at baseline), race/ethnicity/study site (as only Afri-
can American women were recruited in LA county),
education (≤college, >college), BMI (≤25 vs. >25 kg/m²),
smoking status (current vs. never/former),
physical activity in the year prior to diagnosis (MET-h/wk),
menopausal status (pre vs. post), breast cancer stage at
diagnosis (Stages 0 or I vs. Stages II or IIIa), initial breast
cancer treatment (surgery only vs. surgery + radiation or
any chemotherapy), estrogen receptor (ER) status (ER
positive vs. ER negative), tamoxifen use (never vs. ever),
the presence of 1 or more female relatives with history of
breast cancer (Y/N), and activity-limiting comorbidities
(≥1 vs. 0). In the linear models estimating the 10-year
change in MET-h/wk, changes in marital status, employ-
ment, smoking status, and BMI were additionally exam-
ined as covariates.

Statistical analyses were carried out using SAS soft-
ware, Version 9.2 (SAS Institute, Cary, N.C.; ref. 26). All
tests were 2-sided and statistical significance was set at
P < 0.05.

**Results**

Characteristics of HEAL participants according to their
level of recreational aerobic physical activity in the year
prior to diagnosis, as reported at baseline entry into the
study, are presented in Table 1. Overall, 37.5% of women
reported doing no recreational aerobic activity, 28%
reported doing an average of more than 0 to 9 MET-h/
wk, and 34% reported doing more than 9 MET-h/wk on
average during the year prior to their breast cancer
diagnosis.

The mean level of activity in MET-h/wk remained
relatively stable over 5 years of follow-up (mean change
± SD: 0.59 ± 16.2 MET-h/wk), with a dramatic decrease
occurring between 5 and 10 years postdiagnosis (mean
change ± SD: −4.90 ± 14.1 MET-h/wk). This general
pattern was evident irrespective of age, BMI; race/ethnic-
ity, or treatment type (Fig. 1).

A substantial proportion of survivors engaged in little
or no activity throughout the follow-up period, with
42.0%, 40.7%, and 59.1% reporting less than 3 MET-h/wk
(roughly equivalent to walking at an average pace of 2 to
2.9 mph for 1 hour) at 24 months, 5 years, and 10 years
after enrollment, respectively. Figure 2 shows the per-
centage of survivors meeting current U.S. physical activity
levels.

<sup>a</sup> Not measured in participants from LA county

<sup>b</sup>n = 50 missing

<sup>c</sup> Never smoker = smoked <100 cigarettes in lifetime.

Menopausal status at study enrollment was determined on the basis of age, date of last menstruation, hysterectomy, and oophorectomy status, and serum levels of estradiol, estrone, and follicle-stimulating hormone.

<sup>d</sup>n = 1,683, excluded due to: not done (n = 82), borderline (n = 1), unknown (n = 22), not in chart (n = 81)

Female relatives included sisters, mother, daughters, grandmother, aunt, or nieces; 49 women responded ‘Don’t know’ regarding 1 or more female relative diagnosed with breast cancer.

Tamoxifen use included any use up until the 24-month follow-up.
recommendations (23) at each follow-up period. Only 49 women (7.8%) met physical activity guidelines at all timepoints. In contrast, 226 (35.9%) women were insufficiently active to meet physical activity guidelines at any follow-up period, and an additional 135 (21.4%) met guidelines at only 1 timepoint. Sixty-two (9.8%) initially inactive women became sufficiently active to meet current guidelines between baseline and the 10-year follow-up period. Seventy-one women (11.3%) were missing physical activity at 1 or more intermediary timepoints.

In linear regression models, only baseline BMI ($P = 0.029$) was significantly associated with the 10-year

![Figure 1. Average MET-h/wk of moderate-to-vigorous aerobic exercise among breast cancer survivors over 10 years of follow-up according to (i) age, (ii) BMI, (iii) race/ethnicity and study site, and (iv) initial breast cancer treatment.](image1)

![Figure 2. Percentage of breast cancer survivors meeting aerobic physical activity recommendations over 10 years of follow-up.](image2)
change in MET-h/wk of physical activity. After adjusting for baseline age and BMI in logistic regression models, no demographic or prognostic factor was significantly positively associated with the likelihood of meeting physical activity guidelines at the 5- or 10-year follow-up, apart from being Hispanic (5 years only) and meeting the guidelines in the year prior to diagnosis (Table 2). Being African American or a current smoker was associated with a lower relative likelihood of meeting physical activity recommendations at 5 years only. Changes in BMI, smoking status, marital status, or employment status during the 10-year follow-up were not significantly associated with the 10-year change in physical activity (MET-h/wk).

Discussion

In this cohort of breast cancer survivors, mean aerobic recreational physical activity levels remained relatively constant up to 5 years postdiagnosis with a substantial drop between 5 and 10 years. Only a very small proportion (12.3%) of initially inactive women became sufficiently active to meet physical activity guidelines over 10 years of postdiagnosis follow-up, while the majority of breast cancer survivors were insufficiently active to meet current physical activity guidelines throughout 10 years of follow-up.

Prevalence estimates from the 2007 Behavioral Risk Factor Surveillance System (BRFSS), an ongoing population-based survey of U.S. adults 18 years or older, indicated that 60.4% of women self-reported sufficient moderate-to-vigorous activity (all domains) to meet physical activity recommendations (27). The 2008 National Health Interview Survey (NHIS) estimated that 39.9% of women 18 years or older met physical activity recommendations through recreational activities, with little change over the past 10 years (28). Both of these estimates are higher than those observed in our cohort of breast cancer survivors. Similar to our findings, the prevalence of sufficient

activity was lower with advancing age; however, sex-specific estimates by age were not reported, limiting our ability to make direct comparisons.

Our study and both population-based surveys noted above are limited by the reliance on self-reported physical activity data. Recent accelerometer-based estimates of physical activity from the 2003–04 and 2005–06 National Health and Nutrition Examination Survey (NHANES) showed that women without a history of breast cancer participated in moderate-to-vigorous intensity activity for a mean 10.6 min/d, while women with a history of breast cancer participated for a mean 3.7 min/d (29). Thus, the true prevalence of activity in our cohort is likely to be even lower than reported. Future studies of this population will benefit from directly measured physical activity assessment methods and the availability of data from longitudinal and age-stratified population-based cohorts of U.S. women without breast cancer for direct comparison.

Our inability to identify many significant predictors of long-term physical activity participation suggests that the factors influencing physical activity behaviors in breast cancer survivors are complex and may differ from those in the general population. Additional consideration of psychosocial factors and issues related to pain management, fatigue, and specific treatment effects may help to better understand the unique issues faced by cancer survivors and their impact on physical activity participation. Moreover, issues related to perceived neighborhood safety and access to parks and other active recreational opportunities may also be an issue that is particularly relevant to inner city residents such as those from Los Angeles County (30), and could explain, in part, the lower levels of activity reported by African American women in this study.

The finding that prediagnosis physical activity is a strong predictor of postdiagnosis activity up to 10 years after diagnosis is consistent with data from the general population (31) and supports population-wide physical activity promotion. However, a breast cancer diagnosis may provide a unique opportunity to promote the uptake of physical activity among previously inactive women and, therefore, it is important to investigate specific factors associated with physical activity participation in cancer survivors.

In an analysis of women 50 to 79 years of age from the Women’s Health Initiative (5), recreational physical activity between pre- and postdiagnosis increased in 40% of women, remained unchanged in 35%, and decreased in 25%. Although estimates of the magnitude of change were not published, these results are similar to those from the current study in which 44% of women reported a net increase in activity over the 10-year follow-up, while 33% remained unchanged (within 1 MET-h/wk of baseline level) and 23% had decreased recreational activity. Our observation of a sizeable drop in activity participation between 5- and 10-year follow-up, despite no loss to follow-up in the analysis sample, and across virtually all subgroups of women, was somewhat surprising. It seems unlikely that this pattern reflects aging alone, given the consistency and magnitude of the trend across all age groups. Whether this reflects a cohort effect or a unique aspect of the cancer survivorship experience is unclear. The ability to make comparisons to other cancer survivor cohorts will be informative in clarifying this issue. The HEAL cohort represents 1 of the few breast cancer survivor cohorts with repeated assessments of physical activity following diagnosis and with 10-year follow-up data on physical activity and outcomes and, thus, provides valuable information on the long-term trends in recreational physical activity participation in this population. However, the current cohort is likely affected by some degree of healthy subject bias given that the women successfully followed for 10 years were younger (54.3 vs. 56.5 years), were less likely to smoke (11.4% vs. 17%), less likely to have stage II or IIIa disease (51.3% vs. 69.5%), less likely to have 1 or more physical activity-limiting comorbidities (33.7% vs. 23.0%) at baseline, and were more likely to meet physical activity guidelines prior to diagnosis (34.3 vs. 24.0%) than those without physical activity data at the 10-year follow-up. Given the manner in which the HEAL cohort was formed, other limitations of this study include the lack of uniform eligibility criteria between study sites, the different questionnaire for self-reported physical activity assessment used at baseline at 1 of the study sites, incompatible assessments of BMI over time between the study sites and the inability to separate race and study site, given that only African American women were recruited from Los Angeles County and 96% of Hispanic women were recruited in New Mexico. In addition, because complete breast cancer recurrence data is not available for the HEAL cohort, this potentially important confounder could not be considered. Finally, for this analysis, we chose to focus only on patterns of recreational aerobic physical activity rather than total activity, including household, transportation, and occupational activities. However, previous analyses that examined multiple domains of activity in this cohort and others suggest that postdiagnosis recreational physical activity is most strongly associated with breast cancer survival (8, 32).

Although cancer treatment is commonly associated with fatigue, pain, and other adverse side effects (33, 34), interventional studies suggest that women undergoing intensive therapy for breast cancer are able to be physically active during and following treatments (35–39). We did not observe any differences in postdiagnosis physical activity according to treatment type in our cohort. However, while regular physical activity participation is a modifiable lifestyle factor with the potential to improve the cancer survival experience, and is endorsed by the American College of Sports Medicine and American Cancer Society (4), a relatively small proportion of breast cancer survivors are regularly active.

In this cohort, only 8% of breast cancer survivors were sufficiently active to consistently meet physical activity guidelines throughout the 10 years after diagnosis, while 40% to 60% of survivors engaged in little or no activity throughout the follow-up period. Given its health
benefits, ongoing recommendations for physical activity should be made by all healthcare providers caring for breast cancer survivors (40). However, future research should seek to identify the key determinants of exercise across survivorship so that interventions can be appropriately tailored.

Disclosure of Potential Conflicts of Interest
No potential conflicts of interest were disclosed.

Authors’ Contributions
Concept and design: C. Mason, C.M. Alfano, A.W. Smith, M.L. Neuhouser, L. Bernstein, R. Ballard-Barbash, A. McTiernan
Development of methodology: C.M. Alfano, L. Bernstein, R.N. Baumgartner, A. McTiernan
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): C. Duggan, L. Bernstein, K.B. Baumgartner, R.N. Baumgartner, A. McTiernan
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): C. Mason, C.M. Alfano, A.W. Smith, C.Y. Wang, M.L. Neuhouser, R.N. Baumgartner, R. Ballard-Barbash
Writing, review, and/or revision of the manuscript: C. Mason, C.M. Alfano, A.W. Smith, C.Y. Wang, M.L. Neuhouser, C. Duggan, L. Bernstein, K.B. Baumgartner, R.N. Baumgartner, R. Ballard-Barbash, A. McTiernan

Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): M.L. Neuhouser, L. Bernstein, R. Ballard-Barbash
Study supervision: C. Duggan, L. Bernstein, R. Ballard-Barbash, A. McTiernan
