Abstract

Lipid peroxidation generates reactive aldehydes such as trans-4-hydroxy-2-nonenal and malonaldehyde, which form promutagenic exocyclic DNA adducts in human cells and may contribute to diet-related cancers. Using ultrasensitive detection methods, analysis of WBC DNA from volunteers in a dietary study revealed that high intake of ω-6 polyunsaturated fatty acids increased malonaldehyde-derived adducts in male and female subjects. In contrast, etheno adducts (1, N'N'-ethenedeoxyadenosine; 3, N'N'-ethenedeoxyctydine) were not elevated in males but were, on average, 40 times higher in females, displaying a huge intersubject variation in lipid peroxidation-derived DNA damage. Exocyclic DNA adducts are promising biomarkers for examining the hypothesis of possible links between increased intake of dietary ω-6 polyunsaturated fatty acids, DNA damage, and elevated cancer risk for breast, colon, and prostate.

Introduction

At least one-third of all human cancers may be associated with diet (1); dietary fat is thought to be one of the main risk factors because positive correlations between dietary fat intake and increased risk of breast, colon, and prostate cancer have been reported (2–4). Although the role of individual fatty acids in human cancer risk is still poorly understood, epidemiological data have linked a high dietary ω-6 PUFA intake (linoleic acid C18:2), especially in connection with a low ω-3 PUFA (docosahexaenoic acid C22:6) consumption, to an increased risk of breast and colon cancer (5, 6). This can be explained, on one hand, by the findings that ω-6 PUFAs enhance mammary tumorigenesis and tumor cell proliferation in experimentally induced mammary tumors, whereas ω-3 PUFAs can act as growth inhibitors of initiated cancer cells (5, 6). On the other hand, oxidative stress and enhanced peroxidation of PUFAs in cell membranes, often involving hydroxyl radicals, are widely hypothesized to stimulate the development of human malignant diseases (7), raising the question of whether the carcinogenic process could be initiated and/or accelerated through ω-6 PUFA lipid peroxidation-derived DNA damage (8, 9). Recent studies reported the presence of such DNA-damaging adducts in human tissues (10–13). As cell replication before repair of the adducts leads to mutations, DNA adduction is commonly regarded as the initiating step in carcinogenesis.

HNE, one of the major products of lipid peroxidation (14) formed after oxidation of linoleic acid and arachidonic acid (15), is readily oxidized by fatty acid hydroperoxides (16) to form 2,3-epoxy-4-hydroxynonanal, a bifunctional alkylation agent. It reacts with DNA bases to yield etheno adducts, such as 1, N'N'-ethenedeoxyguanosine (17). Likewise, oxidation of rat liver microsomal membranes or of arachidonic acid with cumene hydroperoxide or Fe²⁺ yielded edA and edC in the presence of the respective deoxynucleotides (Ref. 18; see scheme for formation of etheno adducts from PUFA in Fig. 1). The relevance of the three etheno adducts in carcinogenesis is supported by the following: they are promutagenic DNA lesions (19); there is strong evidence that they initiate carcinogenesis by vinyl chloride and urethane (19); edA and edC are elevated in the liver of Long-Evans-Cinnamon rats (animal model for Wilson’s disease), a rat strain that develops spontaneous hepatitis and later hepatocellular carcinoma due to aberrant copper accumulation (20); and much higher hepatic levels of etheno adducts were detected in patients with metal storage diseases at elevated risk for liver cancer, e.g., Wilson’s disease and primary hemochromatosis, as compared to liver DNA from healthy individuals (21). To investigate the impact of a diet high in ω-6 PUFAs or MUFAs on DNA damage, samples from a carefully controlled dietary study (22) were analyzed for promutagenic exocyclic DNA adducts, edA, and edC.

2 The abbreviations used are: PUFA, polyunsaturated fatty acid; HNE, trans-4-hydroxy-2-nonenal; MUFAs, monounsaturated fatty acid; edA, 1,N'-ethenedeoxyadenosine; edC, 3,N'-ethenedeoxyctydine; FA, fatty acid; MA-dG, malondialdehyde-deoxyguanosine adduct; TBARS, thiobarbituric acid reactive substances; TWBC, total WBC; HPLC, high-performance liquid chromatography.
Fatty Acids Enhance content of the oil: 5\% Etheno-DNA Adducts in polyunsaturates, and 13\% (w-3) polyunsaturates of the rapeseed (Brassica saturates, 65\% w-6) polyunsaturates, and traces of (w-3) PUFAs [FA content of the oil: 12\% saturates, 23\% monounsaturates, 65\% (w-6) polyunsaturates, and traces of (w-3) polyunsaturates of the total FAs] for 25 days. The mean daily intakes (% of energy) of \(\omega-6\) PUFA and of \(\omega-3\) PUFA were 12.7 and 0.4 (PUFA group) and 5.5 and 2.1 (MUFA group), respectively. The analysis of plasma phospholipids showed a statistically significant 2.2-fold increase in the \(\omega-6\) PUFA level in the PUFA diet group, compared to the MUFA diet group (23). We have investigated etheno adduct levels in a subset of volunteers from the MUFA diet group (four males and seven females) and PUFA diet group (three males and six females) who were previously analyzed for the MA-dG adduct (Ref. 24; see Table 1 for age and gender distribution of volunteers).

Adduct Measurements. DNA was isolated from TWBCs by phenol-chloroform extraction method (13) and coded. A highly sensitive method (detection limit, \(-4 \) etheno adducts/10\(^{10}\) parent nucleotides) combining immunoaffinity purification with \(^{32}\)P-postlabeling was used to quantitate \(edA\) and \(edC\) in DNA of TWBCs in the form of their 5'-monophosphates (11). The method has been validated against RIA (25), and the coefficient of variation of the method was found to be 20\% (26). In brief, \(-20 \) \(\mu\)g of DNA were hydrolyzed to 3'-deoxynucleoside monophosphates using micrococcal endonuclease and spleen phosphodiesterase. Normal nucleotides were quantitated by HPLC, and \(edA\) and \(edC\) were purified on immunoaffinity columns prepared from monoclonal antibodies (EM-A-1 for \(edA\) and EM-C-1 for \(edC\)), labeled (equivalent to \(\sim 10 \mu\)g of DNA) with \(^{32}\)P[ATP] and T4-polynucleotide kinase to 5'-nucleoside monophosphates, and resolved on polyethyleneimine cellulose plates using two-directional chromatography (11, 20). The spots corresponding to \(edA\), \(edC\), and deoxyuridine 5'-monophosphates were cut from the TLC plates, and the radioactivity was determined by liquid scintillation counting. The absolute levels of adducts were determined by comparing the radioactivity obtained with known amounts of standard; the number of adducts per parent nucleotides were obtained from the ratio of the quantity of etheno adducts measured on TLC to the quantity of parent nucleotides in the sample derived from HPLC analysis (11). The etheno adducts in two samples were further analyzed by reverse-phase HPLC, along with authentic standards of \(edA\) and \(edC\) after labeling with \(^{32}\)P using a radioactivity detector and gradient elution with tert-methylbutylammonium phosphate and methanol.\(^4\)

Results

The isolation of the adducts using antibody immunoaffinity columns (highly specific for the adducts analyzed; Ref. 27) and identical chromatographic properties (Fig. 2, A–C) compared to authentic standards revealed the presence of \(edA\) and \(edC\) in DNA of all human TWBCs for the first time. Two samples were analyzed by reverse-phase HPLC, which further confirmed the identity and the high levels of \(edA\) and \(edC\) detected (Fig. 2D). Mean \(edA\) and \(edC\) levels in males were similar between the two diet groups; however, in female subjects on PUFA diet, the respective means were \(\sim 40\) times higher than those on the MUFA diet, with ranges of 0.13–90.15 \(edA/10^{12} Da\) and 0.06–71.62 \(edC/10^{12} Da\) (Table 1 and Fig. 3). Due to the huge interindividual variation and small number of subjects in the study groups, resulting in a large SD, this sex-dependent difference did not reach statistical significance. However, if one outlier with low adduct levels was omitted, the mean \(edA\) and \(edC\) levels in five of six women on PUFA were significantly

\(^{4}\) I. Velic, J. Nair, and H. Bartsch, Detection of 3',5'-ethenodeoxycytidine and 1,3'-ethenodeoxyadenosine in DNA by reverse-phase HPLC.\(^{32}\)P-postlabeling, in preparation.
Correlation trend for the levels of etheno adducts and MA-dG: regression analysis of all samples showed a significant correlation between edA and edC levels (r = 0.98, P = 1.79 × 10^{-15}), suggesting that, in the DNA of human TWBCs, both adducts were formed by a similar pathway. There was a positive correlation trend for the levels of etheno adducts and MA-dG adducts in the same sample (edC versus MA-dG: r = 0.48, P = 0.01; edA versus MA-dC: r = 0.40, P = 0.08; Table 1). Surprisingly, no correlations were found between etheno adducts and other indices of lipid peroxidation in serum, such as TBARS, MA, and conjugated dienes, that were measured previously (Ref. 23; Table 1). Also, no significant differences were noted for lipid peroxidation indices between the MUFA and PUFA groups (22).

**Discussion**

The high mean levels (26.48/10^7 edA and 22.48/10^7 edC) and the huge variation of etheno adducts in the TWBCs of female subjects on PUFA diet were unexpected. In human liver DNA from healthy subjects (the only other human tissue analyzed thus far), levels were found to be in the range of 0.02-0.28 edA/10^7 dA and 0.06-0.38 edC/10^7 dC (11, 21), whereas in liver cancer-prone patients with metal storage diseases, such as Wilson’s disease and primary hemochromatosis, the hepatic levels were increased 2-3-fold (21). edA and edC adduct levels in TWBCs of males on either MUFA or PUFA diet and in female subjects on MUFA diet were of similar magnitude to those seen in the liver of adult patients with metal storage diseases. The available information by questionnaire on age and lifestyle, such as smoking (none of the participants were regular smokers), alcohol consumption, physical exercise, and the use of oral contraceptives, did not explain the ~40 times increased mean levels of etheno adducts in females on a high PUFA diet. All study subjects were kept on a similar diet (22), except for the type of oil used, whereby PUFA diet led to a ~4 times higher mean daily intake of ω-6 PUFA than the baseline diet.

Therefore, our results clearly indicate that the DNA adduction was due to consumption of a high ω-6 PUFA diet, which resulted in elevated levels of polyunsaturated membrane lipids, implying increased lipid peroxidation (23, 28), although commonly used markers for lipid peroxidation status in serum, such as MA, TBARS, and conjugated dienes, failed to reveal differences between the MUFA and PUFA diet groups (23). However, significantly higher levels of MA-dG adducts were detected previously in the TWBCs of subjects on PUFA diet versus MUFA diet, and the highest mean levels of MA-dG adducts were formed in the DNA of TWBCs of female volunteers in the PUFA dietary group (24).

The marked diet-related difference of etheno adducts in DNA of TWBCs may be due to increased dietary ω-6PUFA intake and hormonal metabolism acting synergistically, which is supported by experimental data: treatment of male Syrian hamsters with the steroidal hormones estradiol and diethylstilbestrol increased both lipid hydroperoxides and MA-DNA adducts in liver and kidney (29). Studies in vitro suggested generation of hydroxyl radicals from estrogens by redox cycling, involving the 4-hydroxylated metabolites and their quinones (30). High intake of ω-6 PUFAs, linoleic acid and arachidonic acid, has been shown to inhibit the detoxification of estrogens by 2-hydroxylation (31) and to elevate 16-α-hydroxylation, leading to metabolites with the potential of redox cycling, thereby possibly enhancing the generation of hydroxyl radicals. Whether these fatty acids also enhance the formation of 4-hydroxylated estrogens is not known.

There was a ~1000-fold variation in etheno adduct levels among female individuals on ω-6 PUFA diet; only one of the female subjects had similarly low levels as males or females on MUFA diet. This interindividual variation may be due to the following host factors: different detoxification rate of HNE, mostly by glutathione S-transferases (32); differences in repair of etheno adducts by specific glycosylases that have been characterized in human tissues, each capable of removing edA and edC (45.4-fold and 75.7-fold, respectively) higher than those on MUFA diet (P < 0.06 and P < 0.05, respectively). Linear regression analysis of all samples showed a significant correlation between edA and edC levels (r = 0.98, P = 1.79 × 10^{-15}), suggesting that, in the DNA of human TWBCs, both adducts were formed by a similar pathway. There was a positive correlation trend for the levels of etheno adducts and MA-dG adducts in the same sample (edC versus MA-dG: r = 0.48, P = 0.01; edA versus MA-dC: r = 0.40, P = 0.08; Table 1). Surprisingly, no correlations were found between etheno adducts and other indices of lipid peroxidation in serum, such as TBARS, MA, and conjugated dienes, that were measured previously (Ref. 23; Table 1). Also, no significant differences were noted for lipid peroxidation indices between the MUFA and PUFA groups (22).

and edC from DNA (33); differential induction of specific cytochrome P-450s that catalyze 4-hydroxylation or 16 α-hydroxylation of estradiol; indeed, a cytochrome P-450 isozyme related to CYP1B1 that increases the 4-hydroxylation of estradiol 5-fold has been identified in human uterine myometrium (34).

On the basis of our results, two important questions can be addressed: Does a high dietary ω-6 PUFA intake also result in increased levels of edA and edC in tissues, such as breast, colon, and prostate, in which fat intake or hormones are suspected carcinogenic risk factors? Is there a synergism between hormonal metabolism and exocyclic DNA adduct formation in humans? Should such adducts be formed via hydroxyl radicals by the ω-6 PUFA pathway in these target organs, they may offer new etiological and mechanistic clues for tumor induction related to dietary fatty acids. Etheno adducts have been proven to be highly miscoding lesions in mammalian cells (35) and are thought to initiate the carcinogenic process through specific point mutations by the known or suspected human carcinogens vinyl chloride or urethane, respectively (19).

Acknowledgments

We thank Dr. A. Barbin, IARC, Lyon, France, for preparing the standards and antigens; Dr. M. Rajewsky and collaborators, University of Essen, Essen, Germany, for providing the antibodies EM-A-1 and EM-C-1 used in immunoaffinity columns; M. Turpeinen, University of Helsinki, for analyzing the serum MA, TBARS, and conjugated dienes; J-L. Fang, Karolinska Institute, Huddinge, for DNA extraction of WBCs; C. Ditrich and I. Kling, Deutsches Krebsforschungszentrum (DKFZ), for excellent technical assistance; and G. Bielefeldt for secretarial help.
