ABSTRACT

Background: We described the demographics, cancer subtypes, comorbidities, and outcomes of patients with a history of cancer and coronavirus disease 2019 (COVID-19). Second, we compared patients hospitalized with COVID-19 to patients diagnosed with COVID-19 and patients hospitalized with influenza.

Methods: We conducted a cohort study using eight routinely collected health care databases from Spain and the United States, standardized to the Observational Medical Outcome Partnership common data model. Three cohorts of patients with a history of cancer were included: (i) diagnosed with COVID-19, (ii) hospitalized with COVID-19, and (iii) hospitalized with influenza in 2017 to 2018. Patients were followed from index date to 30 days or death. We reported demographics, cancer subtypes, comorbidities, and 30-day outcomes.

Results: We included 366,050 and 119,597 patients diagnosed and hospitalized with COVID-19, respectively. Prostate and breast cancers were the most frequent cancers (range: 5%–18% and 1%–14% in the diagnosed cohort, respectively). Hematologic malignancies were also frequent, with non-Hodgkin lymphoma being among the five most common cancer subtypes in the diagnosed cohort. Overall, patients were aged above 65 years and had multiple comorbidities. Occurrence of death ranged from 2% to 14% and from 6% to 26% in the diagnosed and hospitalized COVID-19 cohorts, respectively. Patients hospitalized with influenza (n = 67,743) had a similar distribution of cancer subtypes, sex, age, and comorbidities but lower occurrence of adverse events.

Conclusions: Patients with a history of cancer and COVID-19 had multiple comorbidities and a high occurrence of COVID-19-related events. Hematologic malignancies were frequent.

Impact: This study provides epidemiologic characteristics that can inform clinical care and etiologic studies.
Introduction

Shortly after the emergence of the coronavirus disease 2019 (COVID-19), patients with cancer were reported to be a high-risk population for COVID-19 (1, 2). These patients have an increased susceptibility to infections as a result of their immunosuppressed state, caused by the cancer itself, certain types of chemo- or immunotherapy, or surgery and a higher exposure to healthcare-associated infections (3). In addition, patients with cancer are often older and have additional comorbidities, which might increase their risk of worse COVID-19 outcomes (4).

Prior studies assessing COVID-19-related risks in the cancer population have demonstrated conflicting results. Some studies found that patients with cancer have an increased risk of COVID-19-related hospitalization, admission to intensive care units, and mortality compared with patients without cancer (1, 2, 4, 5), whereas others did not (6, 7). These studies included a limited number of patients with cancer (mostly hospitalized) and used different definitions for cancer (e.g., active cancer, history of cancer), which limit their generalizability. Furthermore, they presented results for models adjusted by (different) arbitrary covariates, without a theoretical framework of confounding variables, which limits the interpretation for descriptive and causal inference purposes (8, 9).

Given that COVID-19 is a novel disease, large descriptive studies are needed to inform public health strategies and clinical care, as well as to provide the groundwork for etiologic studies. In addition, large studies with detailed information of medical conditions and health outcomes, such as thromboembolic events, in patients with cancer and COVID-19 are lacking to date. To fill that gap, we described the demographics, cancer subtypes, comorbidities, and outcomes of patients with a history of cancer and COVID-19. In addition, we compared patients with a history of cancer hospitalized with COVID-19 to (i) patients with a history of cancer diagnosed with COVID-19; and (ii) patients with a history of cancer hospitalized with seasonal influenza (2017–2018) as a benchmark.

Materials and Methods

Study design and setting

This multinational cohort study was part of the CHARYBDIS (Characterizing Health Associated Risks, and Your Baseline Disease In SARS-COV–2) project, designed by the Observational Health Data Sciences and Informatics (OHDSI) community. CHARYBDIS is a large-scale study aiming to characterize individuals with COVID-19 using routinely-collected healthcare data (protocol available at https://www.ohdsi.org/wp-content/uploads/2020/07/Protocol_COVID-19-Charybdis-Characterisation_V5.docx). Twenty-two databases standardized to the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM; ref. 10) have contributed to CHARYBDIS to date. The OHDSI network maintains the OMOP-CDM, and its members have developed a wide range of tools to facilitate analyses of such mapped data (11). Results for this substudy were extracted from the overarching result set on January 29, 2021.

We included those databases reporting on at least 140 subjects with a history of cancer diagnosed and/or hospitalized with COVID-19. This cut-off was established to estimate the prevalence of conditions affecting 10% of the study population with a confidence interval (CI) width of ±5%. The selection process of databases is depicted in Supplementary Fig. S1. Eight databases from Spain and the United States were included in this study.

Spanish data came from the Information System for Research in Primary Care (SIDiap) database, a primary care database from Catalonia, a northeastern region in Spain (12). Data from the United States included Electronic Health Records (EHR) from the hospital setting: Colorado University Anschutz Medical Campus Health Data Compass (CU-AMC-HDC; Colorado), Columbia University Irving Medical Center (CUIMC; New York), Optum-EHR (national; ref. 13), Stanford Medicine Research Data Repository (STARR-OMOP; California), Department of Veteran Affairs (VA-OMOP; national, including mostly veterans with 93% males); and claims data: HealthVerity and IQVIA-OpenClaims (both national). A description of each database is provided in Supplementary Table S1. SIDiap and CUIMC included patients with COVID-19 identified from March to May 2020, HealthVerity, and STARR-OMOP spanned to June 2020, CU-AMC-HDC to July 2020, VA-OMOP to September 2020, and IQVIA-OpenClaims and Optum-EHR to October 2020.

Study participants

We included three non-mutually exclusive cohorts of patients with a history of cancer: (i) diagnosed with COVID-19, (ii) hospitalized with COVID-19, and (iii) hospitalized with seasonal influenza in 2017 to 2018.

We included all patients (regardless of age) with at least 1 year of observation time available prior to index date (i.e., date of start of the cohort). Patients with a history of cancer were defined as those having a record of any malignant neoplasm excluding non-melanoma skin cancer prior to index date. Patients diagnosed with COVID-19 were those having a clinical diagnosis and/or a positive severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) test documented in outpatient or inpatient records. Patients hospitalized with COVID-19 were those who had a hospitalization episode and a COVID-19 clinical diagnosis or positive SARS-CoV-2 test within a time window of 21 days prior to admission up to the end of their hospitalization. We chose this time window to include patients with a diagnosis prior to hospitalization and to allow for a record delay in
diagnoses or test results. Similarly, patients hospitalized with seasonal influenza were those who had a hospitalization episode and an influenza clinical diagnosis or positive test result for influenza in 2017 to 2018 (14). The criteria to define patients with cancer history and COVID-19 and influenza cases can be found in Supplementary Table S2.

Index date for the diagnosed cohort was the date of clinical diagnosis or the earliest test day registered within seven days of a first positive test, whichever occurred first. Index date for both hospitalized cohorts (COVID-19 and influenza) was the day of hospitalization. Therefore, although time windows are slightly different, both COVID-19 cohorts largely overlap, as most individuals in the hospitalized cohort are also included in the diagnosed cohort.

All patients were followed from the index date to the earliest of either death, end of the observation period (15), or 30 days.

Patient characteristics and outcomes
We identified over 15,000 baseline medical conditions based on the Systematized Nomenclature of Medicine (SNOMED) hierarchy, with all descendant codes included (15). In addition, we created specific definitions for comorbidities and outcomes of particular interest (available in Supplementary Table S2). To describe the frequency of cancer subtypes by topographical location (henceforth, referred to as cancer types), we selected 26 cancer types based on the most prevalent cancers in both countries (16). The codes used to identify each cancer type are available in Supplementary Table S3. Of note, although we required all subjects in our study to have at least 1 year of prior history available, all the conditions recorded at any time prior to the index date (including the day prior) were reported.

We report here sex, age, race, antineoplastic and immunomodulating treatment received the month and year prior to index date, and key comorbidities. The only information available for race was the proportion of African American patients, which was reported in four databases (CU-AMC-HDC, CUIMC, Optum-EHR, and VA-OMOP).

The 30-day outcomes of interest in the diagnosed cohort were hospitalization and death (from all causes). In the hospitalized cohorts (COVID-19 and influenza), the outcomes of interest were acute respiratory distress syndrome (ARDS), acute kidney injury (AKI), cardiovascular disease events, deep vein thrombosis, pulmonary embolism, sepsis, requirement of intensive services (identified by a recorded mechanical ventilation and/or a tracheostomy and/or extracorporeal membrane oxygenation procedure), and death (from all causes). SIDIP only reported death and hospitalization, whereas CU-AMC-HDC did not report any outcome.

Analysis
Analysis was performed through a federated analysis approach (15). Following a prespecified analysis plan, an analytical code for the whole CHARYBDIS study was developed and run locally in each site (code available at zenodo.org) (17). Individual-level data remained within host institutions, only aggregate results were provided to the research team. All the results are available for consultation on a regularly updated website as new databases and/or results are added (https://data.ohdsi.org/Covid19Characterization/Charybdis/).

We report results by cohort and database. Demographics, cancer types, comorbidities, and outcomes are reported as proportions along with 95% confidence intervals (CI). To calculate these proportions, a minimum count required of 5 individuals was established to minimize the risk of re-identification of patients. We also report the ranking of the 10 most common cancer types by frequency. In addition, we summarized the prevalence of all the baseline conditions retrieved in a Manhattan-style plot (a type of scatter plot used to represent large numbers of data points).

To compare characteristics between study cohorts, we calculated standardized mean differences (SMD). SMD are independent of sample sizes and can be used to compare the prevalence of dichotomous variables between two groups. An |SMD| < 0.1 indicates a meaningful difference in the prevalence of a given condition (18, 19).

As this study was designed as a detailed descriptive study, statistical modelling was out of scope in the developed analytical packages. Therefore, differences across the groups compared should not be interpreted as causal effects.

We used R version 3.6 for data visualization. All the data partners obtained Institutional Review Board (IRB) approval or exemption to conduct this study.

Results
Lifetime cancer prevalence
Overall, we identified 3,067,116 patients diagnosed and 572,300 patients hospitalized with COVID-19. The lifetime cancer prevalence range across databases was 4% to 25% in patients diagnosed; and 11% to 40% in patients hospitalized (Supplementary Table S4). In addition, 274,557 patients hospitalized with seasonal influenza in 2017 to 2018 were identified (lifetime cancer prevalence range: 18%–39%).

We included 366,050 patients diagnosed (Spain: 8,854; United States: 357,196) and 119,597 patients hospitalized (Spain: 2,610; United States: 116,987) with COVID-19 and cancer history, and 67,743 patients hospitalized (all from the United States) with seasonal influenza and cancer history.

Demographics
The distribution of demographics, comorbidities, and outcomes of both COVID-19 cohorts can be found in Table 1 (95% CI of each condition available in Supplementary Table S5). In the diagnosed cohort, patients were more commonly female (range: 53%–59%), aside from STARR-OMOP (47%) and VA-OMOP (7%). In contrast, in the hospitalized cohort, male slightly predominated in all databases (51%–60%, VA-OMOP: 96%), aside from HealthVerity and Optum-EHR (50% in both). Patients were mainly aged above 65 years in both COVID-19 cohorts but patients hospitalized were consistently older than those diagnosed (Supplementary Fig. S2). In the few databases reporting race, the proportion of African American patients was higher in the hospitalized cohort (9%–35%) than in the diagnosed cohort (6%–29%).

Cancer types
For both COVID-19 cohorts, the frequency of each cancer type is reported in Supplementary Table S6. The top 10 cancer types by frequency are reported in Table 2. In the diagnosed cohort, the most frequent cancers in four databases were breast (SIDIAP: 14.2%; CU-AMC-HDC: 7.3%; Optum-EHR: 6.7%; and STARR-OMOP: 12.3%) and prostate cancer (CUIMC: 6.1%; HealthVerity: 12.2%; IQVIA-OpenClaims: 6.4%; VA-OMOP: 18.1%). In all databases, non-Hodgkin’s lymphoma (NHL) was among the five most common cancers. Bladder, colorectal, leukemia, and lung cancer were among the ten most frequent in at least seven databases.

In the hospitalized cohort, prostate cancer was the most frequent cancer in all databases (equally with NHL in CU-AMC-HDC, 6.4%); aside from Optum-EHR (second most frequent). NHL was among the three most frequent cancers in all databases aside from SIDIAP (fifth

Notes: — indicates data not available. A single individual can have multiple cancer types recorded.
Abbreviation: LOCP: Lip, oral cavity, and pharynx.
most frequent) and STARR-OMOP. Leukemia, liver and lung cancer were also within the top 10 in the majority of databases. We did not observe meaningful differences (i.e., |SMD| > 0.1) when comparing cancer types between the diagnosed and the hospitalized cohorts (Supplementary Fig. S3).

Prior comorbidities

In both COVID-19 cohorts, the most common comorbidities were cardiometabolic conditions, which were more frequent in U.S. databases (especially VA-OMOP) than in the Spanish SIDIAP database. For example, in the United States, the range of hypertension was 52%–87% (Spain: 32%) among diagnosed and 58%–93% (Spain: 33%) among hospitalized patients (Table 1). The prevalence of all the prior conditions summarized is shown in Fig. 1. Several comorbidities were more frequent among patients hospitalized compared with patients diagnosed (SMD >0.1): heart disease and chronic kidney disease (all databases except STARR-OMOP); hypertension and type 2 diabetes (all except SIDIAP and STARR-OMOP; Fig. 2).

Thirty-day outcomes

In the COVID-19 diagnosed cohort, hospitalization in the U.S. databases ranged from 14% to 35% (Spain: 25%) and occurrence of death from 2% to 10% (Spain: 14%). In the COVID-19 hospitalized cohort, outcomes were heterogeneous across databases. ARDS (range 8%–42%) was higher than 30% in three out of six databases (IQVIA-OpenClaims, Optum-EHR, VA-OMOP). Sepsis (6%–25%), cardiovascular disease events (7%–21%) and AKI (10%–17%) were also common. Thromboembolic events were less frequent (deep vein thrombosis: 2%–5%; pulmonary embolism: 2%–4%). Intensive services requirement ranged from 6% to 16%, whereas occurrence of death ranged from 6% to 26% in the United States (Spain: 21%).

Comparison of patients hospitalized with COVID-19 to those with influenza

The characteristics of patients hospitalized with seasonal influenza and the frequency of each cancer type are reported in Supplementary Tables S7 and S8, respectively. Aside from VA-OMOP (96% male), the proportion of males ranged from 45% to 53%, and the majority of patients clustered around the ages of 60 to 85 years old (Supplementary Fig. S4). The proportion of African American patients was lower in the Influenza cohort than in the hospitalized COVID-19 cohort (Optum-EHR: 10% vs. 14%; VA-OMOP: 17% vs. 35%). When comparing the frequency of cancer types between patients with COVID-19 and influenza, we did not observe consistent differences across databases (Supplementary Fig. S5). The distribution of comorbidities was similar in both groups, with few exceptions (Fig. 3A). For example, chronic obstructive pulmonary disease (COPD) was more common among patients with influenza in CU-AMC-HDC, Optum-EHR, and VA-OMOP (Fig. 4A). Aside from CUIMC, outcomes were slightly more frequent in patients with COVID-19 in all databases. ARDS and death were meaningfully more frequent in patients with COVID-19. ARDS ranged from 16% to 42% (COVID-19) versus 14%–30% (influenza), with SMD>0.2 in IQVIA-OpenClaims and Optum-EHR and SMD>0.1 in VA-OMOP. Occurrence of death was higher among patients with COVID-19 compared with patients with influenza in Optum-EHR and VA-OMOP: 6% vs. 1% and 18% vs. 6%, respectively (SMD>0.2; Figs. 3B and 4B).

Discussion

In this multinational cohort study, we described the characteristics of 366,050 patients with a history of cancer and COVID-19, including outcomes rarely reported in this population (e.g., deep vein thrombosis, pulmonary embolism, or acute kidney injury).

Figure 1.
Prevalence of baseline conditions among patients with a history of cancer diagnosed and hospitalized with COVID-19. Each dot represents the prevalence of one baseline condition, with the color indicating the type of condition (i.e., the group, for example blood disease, etc.). Conditions are represented by cohort and database along the x-axis, whereas the prevalence (in %) is displayed on the y-axis. NOTES: Only conditions meeting the minimum count requirement (5 individuals) are shown. N of conditions means the total number of conditions depicted (by cohort and database).
Figure 2.
SMDs of selected baseline comorbidities between patients with cancer diagnosed and hospitalized with COVID-19. SMD < 0 indicates that the prevalence was greater in patients diagnosed, SMD > 0 indicates that the prevalence was greater in patients hospitalized. NOTES: Comorbidities ordered according to SMD descending values in the largest database (IQVIA-OpenClaims). Black-dotted lines indicate an |SMD| of 0.1. SMD calculated for comorbidities meeting the minimum count required (5 individuals) in each database and cohort.

Figure 3.
Baseline comorbidities (A) and 30-day outcomes (B) among patients with history of cancer hospitalized with COVID-19 and with seasonal influenza. NOTES: Comorbidities and outcomes ordered according to descending values in the largest database (IQVIA-OpenClaims). Comorbidities and outcomes are shown if meeting the minimum count required (5 individuals) in each database and cohort. Outcomes not shown due to data not available: all outcomes in CU-AMC-HDC, occurrence of death in CUIMC (influenza cohort) and IQVIA-OpenClaims, intensive services in CUIMC.
In both COVID-19 cohorts, the most frequent cancer types were prostate cancer and breast cancer; hematologic malignancies were also frequent. The proportion of patients that had received anti-cancer therapies the year or the month prior was similar in both cohorts. Comorbidities were common in both cohorts but were higher among those hospitalized. Occurrence of death ranged from 2% to 14% among those diagnosed and from 6% to 26% among those hospitalized. When compared with patients with cancer history hospitalized with seasonal influenza, patients hospitalized with COVID-19 had a similar distribution of age and comorbidities but had more severe outcomes.

In the United States, the lifetime cancer prevalence is 5% (data on the lifetime cancer prevalence in Spain is unavailable to our knowledge; ref. 20), which is lower than our findings in patients with COVID-19 (range 4%–25% in the diagnosed and 11%–40% in the hospitalized cohort). Although comparisons are limited due to different cancer definitions, these prevalences are also higher than prior reports on patients with COVID-19 at hospital settings, with cancer prevalences of 6% to 11% in studies from Europe and the United States (21–24). A Danish study, however, found a lifetime cancer prevalence among patients hospitalized with COVID-19 of 17%, in line with our results (6).

The most lifetime-prevalent cancer types in the United States are prostate and breast cancer (20). These cancer types were also those more frequent in our COVID-19 cohorts. However, hematologic malignancies were more frequent than expected in all our cohorts. For example, in the COVID-19 hospitalized cohort, NHL, leukemia, and multiple myeloma were among the third, fifth, and tenth most common cancers, respectively. However, in the U.S. cancer survivors’ population, NHL is only the fifth/sixth most frequent (men and women, respectively), whereas leukemia is the ninth in men. The overrepresentation of hematologic malignancies in both COVID-19 cohorts raises questions on whether patients with these malignancies are more exposed or more vulnerable to SARS-CoV-2 infection, or both. Prior studies have reported a higher incidence of COVID-19 infection and (25, 26), more worryingly, an increased risk of COVID-19 complications in patients with hematologic malignancies compared with patients with other cancers (5, 25).

We also found that the proportions of patients that had received antineoplastic and immunomodulating agents the year or the month before hospitalization were similar in both cohorts. These results are consistent with findings from other studies (27, 28). However, we found that the proportion of patients that had received antineoplastic agents at any point in the year prior to hospitalization was higher in the COVID-19 cohort (29). This finding may indicate that patients with cancer history are more exposed to SARS-CoV-2 infection or that they are more vulnerable to severe outcomes.

Figure 4. SMDs of selected baseline comorbidities (A) and 30-day outcomes (B) between patients with a history of cancer hospitalized with COVID-19 and with seasonal influenza. SMD<0 indicates that the prevalence was greater in patients with seasonal influenza, SMD>0 indicates that the prevalence was greater in patients hospitalized. NOTES: Comorbidities and outcomes ordered according to SMD descending values in the largest database (IQVIA-OpenClaims). Black-dotted lines indicate an |SMD| of 0.1. SMD calculated for comorbidities and outcomes meeting the minimum count required (5 individuals) in each database and cohort. Outcomes not shown due to data not available: all outcomes in CU-AMC-HDC, occurrence of death in CUIMC and IQVIA-OpenClaims, intensive services in CUIMC.
prior to the index date were similar in both the diagnosed and the hospitalized cohorts. Although this suggests that recent cancer therapies might not be associated with increased COVID-19 severity, this finding must be interpreted with caution due to the overlap between cohorts. However, two studies including over 800 and 900 patients with cancer [from the UK Coronavirus Cancer Monitoring Project (UKCCMP) and the COVID-19 and Cancer Consortium (CCC19), respectively] found no association between cancer therapies and increased COVID-19-related mortality (4, 27).

As expected, patients with cancer history were older and had more comorbidities than overall COVID-19 cases. In a meta-analysis comprising 12,149 COVID-19 cases (mostly hospitalized), hypertension (23%), heart failure (20%), and diabetes (12%) were the most common comorbidities (28). These numbers are substantially lower than our findings. Compared with studies describing patients with cancer, we also found higher prevalences of comorbidities. For example, chronic kidney disease (range 20%–44%), diabetes (24%–59%), and obesity (26%–60%) were higher in our hospitalized cohort than in a study including COVID-19 inpatients with a history of solid cancer (16%, 22% and 10% had chronic kidney disease, diabetes and obesity, respectively; ref. 22). In addition, heart disease, chronic kidney disease, and type 2 diabetes were meaningfully higher among those hospitalized compared with those diagnosed. These conditions have been previously reported as potential risk factors for hospitalization, increased severity, and mortality among COVID-19 cases (29).

Comorbidities should be taken into consideration when designing future studies assessing the effect of cancer on COVID-19-related mortality among COVID-19 cases was 11% in Spain and 5% in the United States (30), which is remarkably lower in the database including cases as of October 2020, Optum-EHR (2% in patients diagnosed, 6% in patients hospitalized). These suggest that studies from the beginning of the pandemic, when testing was limited, might have overestimated the frequency of severe COVID-19 outcomes in this population. In addition, we found that hematological malignancies were more frequent than expected. These findings were foundational for guiding future studies and highlight the importance of protecting patients with cancer while guaranteeing cancer care continuity during the pandemic.

This in-depth characterization revealed that patients with COVID-19 with a history of cancer are mostly aged above 65 years old and have multiple comorbidities that may explain the high frequency of severe COVID-19 outcomes in this population. In addition, we found that hematological malignancies were more frequent than expected. These findings are foundational for guiding future studies and highlight the importance of protecting patients with cancer while guaranteeing cancer care continuity during the pandemic.

Authors’ Disclosures

A.G. Sena reports employment with Janssen R&D and Johnson & Johnson stock ownership. C. Blacketer reports other support from Janssen Research & Development during the conduct of the study, as well as other support from Janssen Research & Development outside the submitted work. S.L. DuVall reports grants from Genomic
Characteristics of 300,000 COVID-19 Individuals with Cancer

Acknowledgments

We would like to acknowledge the patients who suffered from or died of this devastating disease, and their families and carers. We would also like to thank the health care professionals involved in the management of COVID-19 during these challenging times, from primary care to intensive care units. This project has received support from the European Health Data and Evidence Network (EHDEN) project. EHDEN has received funding from the Innovative Medicines Initiative 2 Joint Undertaking (IU) under grant agreement no. 806968. The IU receives support from the European Union’s Horizon 2020 research and innovation program and EFPIA. This research received partial support from the National Institute for Health Research (NIHR) Oxford Biomedical Research Centre (BRC), U.S. National Institutes of Health (NIH), U.S. Department of Veterans Affairs, Janssen Research & Development, and IQVIA. This work was also supported by the Bio Industrial Strategic Technology Development Program (20001234) funded by the Ministry of Trade, Industry & Energy (MOTIE, Korea) and a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant no. HI16C0992). Bill & Melinda Gates Foundation (INV-016201), and the Direcció General de Recerca i Innovació en Salut from the Department of Health of the Generalitat of Catalonia. E. Roel is supported by Instituto de Salud Carlos III (grant no. CM01900774). W.U.R. Ahmed reports funding from the NIHR Oxford Biomedical Research Centre (BRC), Azur Foundation, Wellion Foundation, and the Royal College of Surgeons of England. A.G. Sena and L. Hester are employed by Janssen Research and Development, LLC. J. Jonnagaddala reports grants from the National Health and Medical Research Council (APP1192469). M. Gong and Y. Zhang report grants from National Key Research & Development Program of China (Project No. 2018YFC0116901). V. Subbian reports funding from the National Science Foundation, Agency for Healthcare Research & Quality, National Institute of Health, and the State of Arizona. A. Prats-Uribé is supported by Fundación Alfonso Martin Escudero (grants nos. RR/502(266), MINECO/FEDER, EU) and the Medical Research Council (grant nos. MR/K501256/1, MR/N013468/1). S.L. DuVall, K.E. Lynch, and M.E. Matheny report funding from the Department of Veterans Affairs (VA) Informatics and Computing Infrastructure (VINCI, VA HSR RES 13-457). No funders had a direct role in this study.
