Abstract

Background: Occupational exposures are known risk factors for lung cancer. Role of genetically determined host factors in occupational exposure–related lung cancer is unclear.

Methods: We used genome-wide association (GWA) data from a case–control study conducted in 6 European countries from 1998 to 2002 to identify gene–occupation interactions and related pathways for lung cancer risk. GWA analysis was performed for each exposure using logistic regression and interaction term for genotypes, and exposure was included in this model. Both SNP-based and gene-based interaction P values were calculated. Pathway analysis was performed using three complementary methods, and analyses were adjusted for multiple comparisons. We analyzed 312,605 SNPs and occupational exposure to 70 agents from 1,802 lung cancer cases and 1,725 cancer-free controls.

Results: Mean age of study participants was 60.1 ± 9.1 years and 75% were male. Largest number of significant associations ($P \leq 1 \times 10^{-5}$) at SNP level was demonstrated for nickel, brick dust, concrete dust, and cement dust, and for brick dust and cement dust at the gene-level ($P \leq 1 \times 10^{-4}$). Approximately 14 occupational exposures showed significant gene–occupation interactions with pathways related to response to environmental information processing via signal transduction ($P < 0.001$ and FDR < 0.05). Other pathways that showed significant enrichment were related to immune processes and xenobiotic metabolism.

Conclusion: Our findings suggest that pathways related to signal transduction, immune process, and xenobiotic metabolism may be involved in occupational exposure–related lung carcinogenesis.

Impact: Our study exemplifies an integrative approach using pathway-based analysis to demonstrate the role of genetic variants in occupational exposure–related lung cancer susceptibility. *Cancer Epidemiol Biomarkers Prev; 24(3); 1–10. ©2015 AACR.*

Introduction

Lung cancer is the most common cancer worldwide; with an estimated 1,600,000 new cases and 1,380,000 deaths annually

(1, 2). The most important risk factor for lung cancer is tobacco smoking; with more than 90% of lung cancer in men attributed to smoking (3, 4). In addition, environmental and occupational risk factors also contribute to the burden of lung cancer. The attributable fraction for lung cancer from occupational exposures has been reported to be as high as 7.9% to 16.5% in men and 1.4% to 4.5% in women (5–7) with asbestos, diesel engine emissions, and other mixtures of polycyclic aromatic hydrocarbons, crystalline silica, arsenic, and some heavy metals being some of the major contributors (8). The mechanism by which occupational exposures contribute to increased lung cancer risk is not well understood, but the suggested mechanisms, which likely differ between carcinogenic agents, include DNA damage, chronic increase in inflammatory cytokines or growth factors, or due to impairment in DNA repair (7).

There is evidence to suggest that inherited genetic factors influence the development and progression of lung cancer. A family history of lung cancer in a first-degree relative is associated with a significantly increased risk of lung cancer (relative risk, 1.95; ref. 7). This association is stronger in never smokers than in current smokers. Recent genome-wide association (GWA) studies of lung cancer have shown variations at 15q24-25.1 as a determinant of increased lung cancer risk (9–11). A second lung cancer locus has been identified through the GWA studies at 5p, and includes the genes encoding TERT and CLMPTL1. In addition to these loci, there is evidence

implicating loci at 6p, 13q, and 22q as a risk factor for lung cancer (12–14).

Although GWA studies have been successful in identifying genes or loci associated with disease, the identified variants only explain a small proportion of the overall genetic variance (15). Gene–environment interactions may account for the missing heritability of the complex diseases (16). Genetically determined host factors may also play an important role in the pathogenesis of lung cancer associated with exposure to occupational risk factors. However, data looking at the complex interplay between genetic factors and exposure to occupational agents are limited. Possible mechanisms by which occupational exposures can interact with genetic variations leading to increased lung cancer risk include carcinogen detoxification, activation of carcinogens, and the processes of DNA damage and repair. We used the data generated in the framework of a recent GWA study to identify interactions of genetic variants and occupational exposures in lung cancer risk based on the INCO-Copernicus study. As part of this analysis, we studied gene–environment (G × E) interactions at both SNP and gene level. Pathway-based approach complements single SNP analysis by examining the cumulative contribution of functionally related genes or loci with an outcome, thereby incorporating biologic knowledge into the analysis (17, 18). Therefore, we also performed a pathway-based analysis to provide an insight into possible biologic associations.

Materials and Methods

Study participants

The INCO-Copernicus study is a case–control study conducted during the period 1998 to 2002 in 6 Central and Eastern European countries in Hungary, Poland, Slovakia, Czech Republic, Romania, and Russia (19, 20). The International Agency for Cancer Research (Lyon, France), was responsible for the overall coordination of the study. The study population comprised of all newly diagnosed lung cancer cases (age <75 years) at the participating hospitals. A comparable group of hospital-based subjects (community-based in one of the Polish centers) matched by gender and age formed the control arm of the study. Eligible subjects (cases and controls) must have resided in the study area for at least 1 year before recruitment and the interview had to be conducted within 3 months of diagnosis. Patients with smoking-related conditions or other cancers were not considered eligible. Case patients and control subjects underwent an identical in-person interview during which they completed a detailed questionnaire and provided blood samples. Occupational histories were collected by trained interviewers using semistructured questionnaires. Exposure to 66 occupational agents was coded blindly of case–control status by local groups of experts, comprising industrial hygienists and occupational physicians, based on the detailed questionnaires and knowledge on working conditions in the study areas. For the purpose of this interaction analysis, ever exposure was defined as employment for at least 6 months in a job entailing exposure above background level. Participants with missing occupational exposure data ($n = 647$) and those failing quality control steps ($n = 404$) as described below were excluded.

Genotyping and quality control

Genotyping on 4,578 subjects (1968 lung cancer cases and 2610 controls) was performed using Illumina Sentrix Human-Hap300 BeadChip containing 317,139 SNPs (10, 21). As part of quality control, pairs of individuals with an identity-by-state (IBS) value >0.98 were considered to be indicative of a duplicate sample and from these pairs; one of the individuals was randomly removed from the data. Samples with more than 5% missing genotype were also excluded. In addition, samples whose reported sex did not match with the inferred sex based on the heterozygosity rate from the X chromosomes were removed (22). Samples with less than 70% European ancestry as determined by STRUCTURE (23, 24) and high degree of relatedness (sib-pairs and half-sib pairs, IBS > 0.50) were also excluded. Limited extent of population stratification as confirmed by principal components analysis was confirmed and outliers were removed (25). SNPs with less than 95% completion rate or departure from Hardy–Weinberg equilibrium ($HWE < 10^7$) were also excluded.

SNP-based analysis

Single marker association analysis was performed for each exposure using an unconditional logistic regression model. The model included additive SNP effect, age, gender, smoking history, country/center, binary occupational exposure, disease-risk score, and interaction term for genotypes and exposure. The P value of the interaction term was used to assess the significance of the interaction between genetic variants and occupational exposure, and a P value of $\leq 1 \times 10^{-5}$ was considered to be significant. The disease risk score was calculated for each exposure using history of exposure to other occupational exposures to estimate the probability of disease occurrence in the absence of the exposure (26). All analysis was performed using PLINK (27). SNPs were mapped to associated genes using reference SNP location from UCSC Genome Browser hg18 assembly with ±20 kb gene boundaries.

Gene-based analysis

The versatile gene-based association test was used to calculate gene–level interaction P values (28). This test incorporates information from a full set of markers (or a defined subset) within a gene and accounts for linkage disequilibrium (LD) between markers by using simulations from the multivariate normal distribution. SNPs are assigned to 17,787 autosomal genes according to UCSC Genome Browser hg18 assembly with ±50 kb gene boundaries. The gene-based test statistic is the sum of all of the χ^2 1 degree of freedom statistics within that gene, which are calculated from SNP-based P values. Results obtained using this method have been shown to be equivalent to those obtained via permutation. As this was a gene–environment interaction analysis, we opted for a slightly looser P value threshold of $\leq 1 \times 10^{-4}$, compared with Bonferroni-corrected P value threshold of $<2.8 \times 10^{-6}$ (0.05/17,787).

Pathway-based interaction analysis

We used three complementary pathway-analysis methods, which are listed below. Pathways or gene sets were considered to be significantly enriched, if the adjusted P value or FDR was ≤ 0.05, using any one method, or unadjusted P value of ≤ 0.05 using at least two methods.

1. Improved gene set enrichment analysis (IGSEA4GWAS; ref. 29): In IGSEA, max statistics or $-\log(P\ value)$ of closely spaced SNPs in a gene are used to represent the gene. The ranked gene list with corresponding representing values is used to calculate each gene set's enrichment score (ES), that

is, a Kolmogorov–Smirnov like statistics with weight 1. SNP label permutation is performed to correct for gene and gene-set variation, and significance proportion-based ES (SPES) is calculated. SPES emphasizes on total significance coming from high proportion of significant genes. This method has been shown to have improved sensitivity compared with GSEA, and is more appropriate for study of the combined effects of possibly modestly associated SNPs/genes. This method uses a comprehensive pathway/gene set database with pathways integrated and curated from a variety of resources, including KEGG (Kyoto Encyclopedia of Genes and Genomes pathway database), Biocarta, GenMAPP etc. Pathways with <20 genes or >200 genes were excluded from further analysis, and SNPs were mapped to genes with ±20 kb boundaries. FDR was used for multiple testing correction with FDR $\leq$ 0.05 considered to be significant.

2. Interval-based Enrichment Analysis Tool for GWAS (INRICH; ref. 30): This method detects enriched association signals of LD-independent genomic regions within biologically relevant gene sets. To ensure that multiple, adjacent SNPs that potentially tag the same causal variant are analyzed as one independent association unit, LD-independent intervals were generated around the associated SNPs using PLINK 1.07, and enrichment test was conducted using KEGG database and Gene Ontology terms. A permutation approach is used to calculate empirical significance P values for each gene set. This method, therefore, adjusts for confounding factors like varying gene size, SNP density, LD that is not usually accounted for by GSEA. Multiple testing corrections are achieved via a second, nested round of permutation to assess the null distribution of the minimum empirical P value across all tested gene sets. Adjusted P value of $\leq$0.05 was considered to be significant.

3. Systematic biologic knowledge-based mining system (KGG; ref. 31, 32): Using the hybrid set-based test approach, SNPs in a gene set are partitioned into LD-based blocks. For each of these blocks, the extended Simes test (GATES; ref. 33) is used to calculate the block-based P value for association and to mark the key SNP from which this was derived. Finally, the scaled χ^2 test is used to combine the block-based P values into a single test statistic . Canonical pathways (880; including from KEGG, BioCarta and Reactome) collected from the MsigDB database were used to annotate pathways. Gene-set P value of <0.0001 was considered to be significant (0.05/880 = 0.000056 on calculating FDR).

Results

Patient characteristics

A total of 3,527 participants (1,802 lung cancer cases and 1,725 controls) were included in our analysis; their baseline characteristics are reported in Table 1. The mean age of the study participants was 60.1 ± 9.1 years, and there was no difference in mean age between cases and controls. Cases had higher percentage of males (77.5% vs. 72.4%; $P < 0.0001$) as compared with controls. As expected, there was a marked difference between cases and controls in smoking habits. Of note, 71.3% of lung cancer cases had non–small cell lung cancer with squamous cell cancer (42.5%), forming the predominant histologic type followed by adenocarcinoma (22.6%). The percentage of cases and controls with ever exposure to each occupational agent is listed in Supplementary Table S1. Seventeen established or suspected lung carcinogens that were included in our analysis include arsenic, asbestos (amphibole and chrysotile), metals (arsenic, cadmium, chromate, chromium, nickel, and their compounds), chlorinated solvents, diesel engine emissions, organic dust, and silica (brick dust, cement dust, concrete dust, respirable-free crystalline silica, and sand). In addition, 49 other occupational agents with a possible relation to lung carcinogenesis were also included in this analysis.

SNP-based association analysis

After quality control, 312,605 SNPs were included in our analysis. The SNPs that showed interaction P values (G × E) < 1×10^{-5} are reported in Supplementary Tables S2 and S3. Of the established/suspected lung carcinogens, the largest number of significant associations ($P \leq 1 \times 10^{-5}$) was demonstrated for nickel and compounds, brick dust, concrete dust, and cement

Malhotra et al.

dust. Asbestos (and chrysotile), chromium and compounds, organic dust, and sand showed association with at least three SNPs each. Many exposures showed multiple SNPs associated within the same loci or gene—asbestos (three SNPs on WDR6), chrysotile (PKNOX2), nickel and compounds (CGNL1 and SUSD5), live animals (SLC35F5), cement dust (CD46 and CPA3), and sand (LBA1). No significant association was found for amphibole asbestos, arsenic and compounds, cadmium and compounds, chromate and compounds, and chlorinated solvents. Of the other occupational exposures, significant SNP-based associations were observed for hard-wood dust (19 SNPs), soft-wood dust (11 SNPs), inorganic acid mist (10 SNPs), inorganic acids mist (9 SNPs), animal viruses (seven SNPs with four corresponding to CNTN1 gene, and three to NFIC gene), and plastics pyrolysis fumes (13 SNPs). Of note, diesel and kerosene exposure showed a significant association with 23 SNPs within a region on chromosome 15 with 13 SNPs mapped to the gene MYO9A.

Gene-based association analysis

Genes with G × E interaction P values $\leq 1 \times 10^{-4}$ for each occupational exposure are listed in Table 2 and Supplementary Table S4. Of the established/suspected carcinogens, we did not find any significant gene-based interaction for asbestos, arsenic and compounds, nickel and compounds, chromium and compounds, cadmium and compounds, and chlorinated solvents. The largest number of significant associations was demonstrated for brick dust (AQP8, CPA4, and CPA5) and cement dust (ANKRD56, CD46, DAZAP2, LOC57228, and RTN4R). Associations that were significant in both SNP-based and gene-based analysis were noted for gene CD46 for cement dust, LBA1 for sand, and five genes on chromosome 15, including MYO9A ($P = 0.00006$) for diesel and kerosene. Of the other occupational exposures, significant gene-based associations were found for stainless steel dust, soft-wood dust, inorganic acid mist, and plastics pyrolysis fumes.

Significant genomic regions identified and associated genes with each region are listed in Supplementary Table S5. Genomic regions with largest number of significant genes identified for at least one of the gene–occupation interactions are 1q23.2, 1q24.1 to 1q24.2, 6p21.31, 11q13.2, 15q23, and 19p13.3. Main categories of proteins coded for by the significant genes identified in our

analyses are listed in Supplementary Table S6 using the PANTHER (protein analysis through evolutionary relationships) Classification System (34, 35). A majority of the proteins coded by these genes are either involved in the transcription process (either in nucleac acid binding or as a transcripton factor), or function as a receptor or enzyme modulator.

Pathway–level interaction analysis

The most significant pathways (P value ≤ 0.05 after adjusting for multiple comparisons) related to interaction analysis between genetic variants and each occupational exposure are reported in Tables 3 and 4, and Fig. 1. Most of the significant pathways were related to signal transduction pathways, which play an integral role in environmental information processing, immune processes, and metabolism of exogenous agents.

1. Signal transduction pathways: MAPK pathway or ERK1–ERK2 pathway showed significant associations with exposure to chromate and compounds, chromium and compounds, and brick dust, as well as with five other potential carcinogens (coal and coke combustion fumes, diesel and kerosene, inorganic insulation dust, iron, and formaldehyde). Both chromium and chromate compounds were significantly associated with the Wnt pathway. In addition, animal viruses were also associated with this pathway. Chromate also showed significant association with the TNF receptor (TNFR) pathway. Of the silica products, both brick and cement dust were also associated with the TNFR1 pathway. Although arsenic and compounds showed no significant SNP-based or gene-based interaction associations, they did show significant association with the FC epsilon receptor signaling pathway (adjusted P value of 0.02). Nickel and compounds showed significant enrichment for nuclear factor-KB (NFKB) and hedgehog signaling pathways. The NFKB pathway was also associated with chrysotile exposure.

2. Pathways involved in immune regulation: Chromate and compounds showed association with B-cell activation pathways (P value of 0.0007) and both wood dust and soft-wood dust showed association with antigen processing and presentation. Petroleum products like gasoline, and diesel and kerosene showed significant associations with T-cell

activation pathways. T-cell pathways were also enriched for soot, inorganic insulation dust, and inorganic pesticides.

3. Xenobiotic metabolism (metabolism of potential carcinogens): Phase I or cytochrome 450 metabolism was enriched for diesel engine emissions (adjusted P value of 0.06) and for plastics pyrolysis fumes. In addition, phase II metabolism was enriched for chromium and compounds.

4. Others: Other enriched pathways included those related to p53 (chromate and compounds), DNA replication (nickel and compounds, concrete dust, and petroleum oil combustion fumes), apoptosis (animal feeding, hard-alloys dust, and asphalt-bitumen fumes), cell death (animal feeding), and DNA repair (carbon black dust).

Discussion

Knowledge about the role of interactions between genetic factors and occupational exposures in lung carcinogenesis is limited. To our knowledge, our study is the first to use GWA data to analyze gene–occupation interactions between a large range of occupational exposures and GWA-derived genetic variants in determining lung cancer susceptibility. In addition to SNP-based and gene-based analysis, we also performed pathway-based analysis to identify possible causal pathways involved. We found that pathways related to signal transduction (especially MAPK and Wnt), immune response, and xenobiotic metabolism were significantly enriched in relation to the studied gene–occupational exposure interactions. We found significant association at SNP-based, gene-based, and pathway-based analyses in our study, which indicate that interaction between genetic variants or polymorphisms and occupational agents may play a role in determining an individual's susceptibility to lung cancer.

Previous GWA studies have shown multiple loci to be associated with lung cancer susceptibility especially those related to 15q, 5p, and 6p with $P < 5 \times 10^{-8}$ (9–13). However, these explain

Malhotra et al.

Abbreviations: KGG, knowledge-based mining system for genome-wide genetic studies; PID, pathway interaction database; STKE, signal transduction knowledge environment.

only a small proportion of individual variation in lung cancer susceptibility, and gene–environment interactions may account for the missing variation (15, 16). A number of studies looking at gene–environment interactions for smoking have found strong evidence of interactions with smoking (36, 37). However, hardly any studies have looked at gene–environment interactions for occupational exposures in lung carcinogenesis, although occupational risk factors have a significant contribution to the burden of lung cancer (5–7). Wei and colleagues (38) conducted a study to determine genome-wide gene–asbestos exposure interaction on lung cancer risk at levels of SNPs, genes, and pathways. Although they reported limited power to detect gene–environment interactions at the SNP and gene levels, their pathway-based approach did show significant associations in the immune function regulation–related pathways. Our study also demonstrates significant gene–environment interactions in immune system pathways for many exposures such as heavy metals and petroleum products, but not for asbestos.

Our study looked at gene–environment interactions for nearly 70 occupational exposures, and has important implications as research in this area till now has been limited. We used both SNP-based and gene-based association methods as both have their own advantages and disadvantages. The SNP-based method can identify significant loci with only a small number of significant SNPs, but may miss detecting SNPs with weak marginal effects, but a strong joint effect. Gene-based analysis may identify these genes with more than one causative variants with marginal levels of significance that are often indistinguishable from random noise in the initial SNP-based GWAS results (28).

One limitation of gene–environment interaction studies is the need for larger sample size and more than 10,000 case–control pairs may be required to detect significant interactions (39). Of the hundreds of published GWASs, few have reported significant SNP-level gene–environment interactions (40). Current GWAS design may not provide enough statistical power to detect interactions at the single SNP level, as it mainly focuses on the main effect of an SNP. This is especially true for analysis of rare variants with weak main effects that may not be detectable in the analysis of genetic marginal effects only (41). Therefore, we included occupational exposures for which main genetic effects have not yet been elucidated also in our analysis.

As our study is exploratory and hypothesis-generating, we used less stringent threshold p-values for significance after correcting for multiple comparisons. In addition, as SNP-based or gene-based associations may miss markers that may contribute additively and incrementally to cancer risk by participating in common pathways and networks underlying disease susceptibility, we performed pathway analysis to identify potential biologic causal pathways (17, 18). There is limited agreement about the optimum methods to identify top-ranked pathways. Studies have compared different pathway analysis methods and have found only a modest degree of overlap between top pathways chosen by each method (42, 43). Because different pathway analysis methods can produce different results using the same dataset, it is recommended to use more than one method when examining pathway associations with disease risk (42, 43). Therefore, we used three different but complimentary pathway analysis methods with different approaches to pathway analysis.

Our results suggest that polymorphisms related to pathways involved in signal transduction (especially MAPK, Wnt, and TNF), immune response, and metabolism of exogenous agents may increase individual's risk to lung cancer on being exposed to certain occupational agents. Although the genes involved in these pathways have been shown to be involved in lung cancer pathogenesis (44–48), data showing the association of these pathways in relation to interactions between genetic polymorphisms and occupational exposures are lacking. Our study is one of the first studies to identify this relationship, and further studies in this area are needed. Also, although we only studied potential lung carcinogens in the occupational settings, our results can potentially be extrapolated to individuals with history of exposures to these agents in other settings, like at home or in the environment.

One main concern of a gene–environment study is the potential to misclassify environmental or exposure variable that can impact power and generate bias. A major strength of our study is that it was designed specifically to measure occupational exposures, and detailed occupational exposure assessment was done by local expert panels using detailed semistructured questionnaires. Another strength of our study is that we conducted analysis at the levels of SNPs, genes, and pathways, thereby reducing the chance to miss weaker associations without compromising on adjustments for multiple testing. One limitation of our study is that it does not include validation of the results using an independent dataset. This is mainly because detailed occupational data are not usually collected as part of GWA studies in lung cancer, and therefore, we did not have access to similar datasets to replicate our findings. Also, because of limited sample size, we were unable to perform stratified interaction analysis by level or
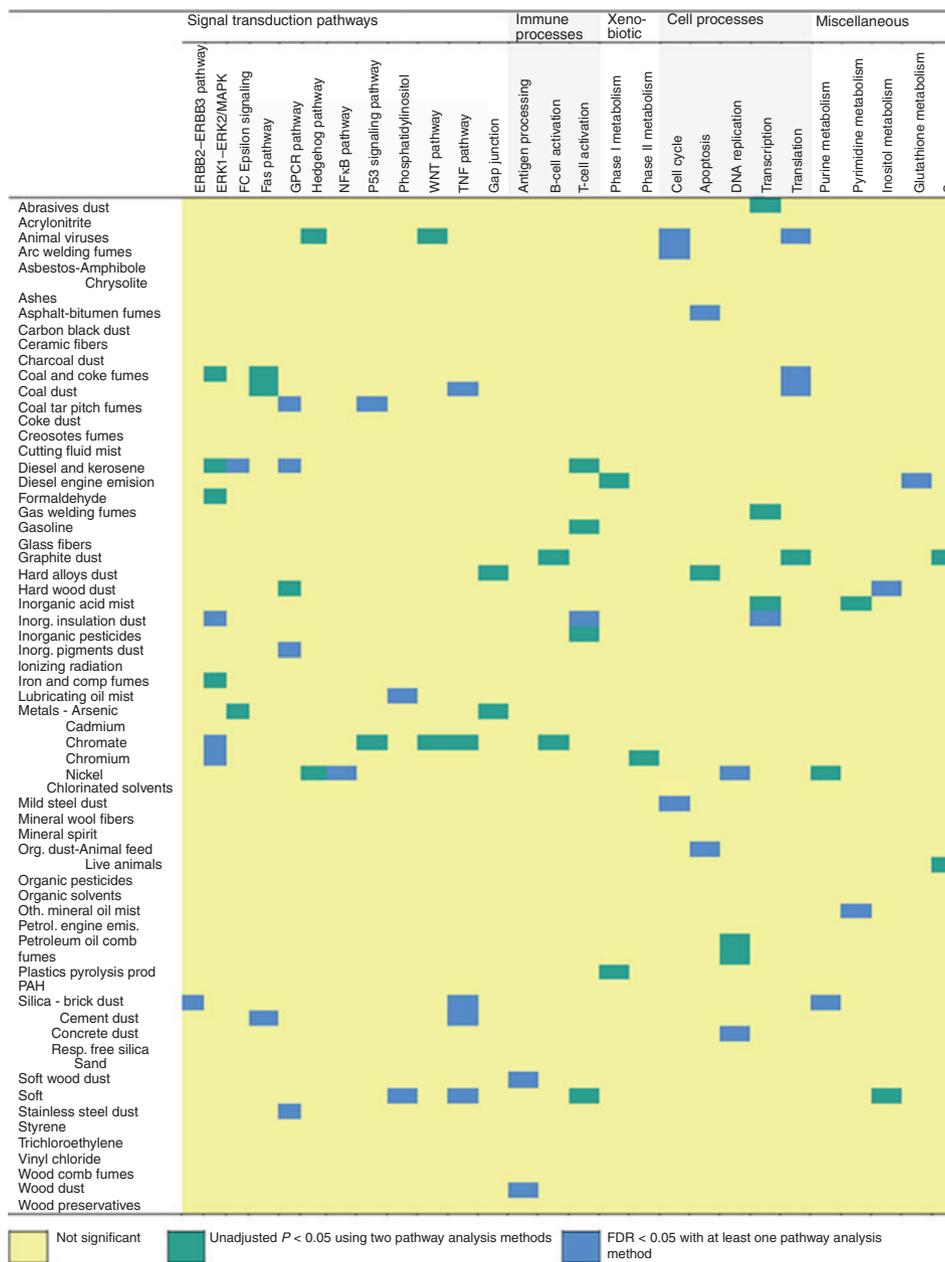

Malhotra et al.

Figure 1.
Pathway-based analysis using occupational exposure interactions.

duration of exposure, histology, gender, or country. However, with 1,802 lung cancer cases and 1,725 controls, the sample size in our study was at least similar, if not larger than major published lung cancer GWA studies. Another potential limitation of our study is that, although cases and controls were matched during initial study enrollment, this may not be applicable to the genotypic analysis as subjects were excluded before performing the GWA analysis using quality control criteria. We used unconditional logistic regression for analysis, which does not account for preferential sampling through the cases. However, unconditional logistic regression has been reported to be robust to gene–environment correlation (49). In addition, there is no single method that has been validated to outperform other methods for gene–environment interaction analysis (39). In addition, an important

limitation of the pathway-based approach for GWA analysis is the incomplete annotation of the human genome (32). Also, the pathway analysis methods used in our study have not been compared with each other previously to ascertain the degree of overlap in detecting significant associations using these methods.

In conclusion, our study exemplifies an integrative approach using SNP-based, gene-based, and pathway-based analyses to demonstrate that genetic variants may play an important role in determining an individual's susceptibility to lung cancer in response to occupational exposures. Our results suggest that pathways related to signal transduction, immune processes, and xenobiotic metabolism may contribute to this increased susceptibility: They should be interpreted as hypothesis generating and request validation in independent datasets. Our study also

showed that pathway-based approaches may help in elucidating potentially important associations and causal pathways for gene–environment interaction analyses.

Disclosure of Potential Conflicts of Interest

P. Boffetta has provided expert testimony for various entities with interest in agents included in the present study (diesel exhaust, mineral fibers, and asbestos). No potential conflicts of interest were disclosed by the other authors.

Authors' Contributions

Conception and design: J. Malhotra, P. Brennan, D. Zaridze, P. Rudnai, P. Boffetta
Development of methodology: J. Malhotra, P. Rudnai, E. Fabianova, P. Boffetta
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): P. Brennan, D. Zaridze, N. Szeszenia-Dabrowska, B. Świątkowska, P. Rudnai, J. Lissowska, E. Fabianova, D. Mates, V. Bencko, I. Stücker, L. Foretova, V. Janout, P. Boffetta
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): J. Malhotra, S. Sartori, J. Lissowska, P. Boffetta

Writing, review, and/or revision of the manuscript: J. Malhotra, P. Rudnai, J. Lissowska, E. Fabianova, V. Bencko, L. Foretova, V. Janout, P. Boffetta
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): J. Malhotra, B. Świątkowska, J. Lissowska, V. Gaborieau, L. Foretova
Study supervision: J. Lissowska, E. Fabianova, P. Boffetta
