Abstract

Background: Host immune response may predict the course of colorectal cancer. We examined the survival of 468 colorectal cancer patients associated with two tumor-infiltrating immune biomarkers, the number of cytotoxic T lymphocytes (CTLs), and the activated CTLs, as reflected by the number of cells expressing granzyme B (GZMB) in the prospective Iowa Women’s Health Study.

Methods: Using paraffin-embedded tissue samples, we constructed and immunostained tumor microarrays with CD8 (for CTL) and GZMB antibodies. We scored CTL and GZMB densities in tumor epithelial and stromal tissues and also created a composite score for each biomarker (sum of the scores across tissue compartments). Cox regression estimated the HR and 95% confidence intervals (CI) for all-cause and colorectal cancer–specific death associated with each composite score.

Results: CTL and GZMB composite scores were positively correlated ($r = 0.65$) and each biomarker was inversely correlated with stage at diagnosis. Both composite scores were higher in proximal colon tumors and tumors characterized by MSI-high, CIMP-high, or BRAF mutation status. HRs (95% CI) were 0.53 (0.38–0.75; $P_{\text{trend}} = 0.0004$) and 0.66 (0.51–0.86; $P_{\text{trend}} = 0.002$) for all-cause death, respectively, and 0.30 (0.18–0.51; $P_{\text{trend}} < 0.0001$) and 0.41 (0.27–0.63; $P_{\text{trend}} < 0.0001$) for colorectal cancer–related death, respectively. Including CTL and GZMB scores simultaneously in the model significantly improved the predictive performance of the models for all-cause and colorectal cancer–related death.

Conclusions: Higher tumor infiltration with CTL and GZMB cells is associated with improved all-cause and cancer-specific survival of colorectal cancer patients.

Impact: Both the number of CTLs and GZMB appear to be useful prognostic factors in colorectal cancer, irrespective of stage.

Cancer Epidemiol Biomarkers Prev; 26(4); 1–10. ©2016 AACR.

Introduction

Colorectal cancer is a leading cause of cancer-related death in the United States. The survival rate for colorectal cancer is improving, but 35% of patients still die within 5 years after diagnosis (1). Decisions about treatment for colorectal cancer are based largely on the tumor–node–metastasis (TNM) staging system, but there is considerable variability of outcomes within stages (2–4). Hence, to accurately determine the prognosis and optimize treatment, it is essential to establish additional factors that predict and improve the stratification of colorectal cancer patients (5, 6). Classification of colorectal cancer tumors by molecular characteristics [e.g., chromosome instability, microsatellite instability (MSI), CpG island methylator (CIMP) phenotype, and mutation in $BRAF$ and/or $KRAS$ genes] has emerged as an important prognostic tool in colorectal cancer (reviewed in refs. 6–12). The most consistent data have been reported for MSI status: MSI-high versus MSI-low/MSS (microsatellite stable) tumors have been associated with 35%–40% better survival (8, 10), and MSI status may inform decisions regarding adjuvant therapy for specific stages (13).

Another opportunity to refine colorectal cancer prognostication and clinical management is to consider immune activity in the tumor microenvironment. In a series of landmark studies, the group of Galon and colleagues demonstrated that the type, density, and location of total lymphocytes (CD3+), cytotoxic T lymphocytes (CTL, or CD8+), and memory T lymphocytes correlated with disease-free and overall survival in colorectal cancer patients, and indicated the superiority of immune infiltrates over TNM staging in predicting patients’ survival (14, 15). Subsequent studies have confirmed the importance of tumor lymphocytes as a prognostic factor in colorectal cancer (reviewed in refs. 12, 16, 17).
Many studies have examined the role of tumor-infiltrating CTLs in colorectal tumors, and eight of them have been collectively evaluated in a recent meta-analysis that concluded that high versus low CTL numbers in the tumor center, stroma, and invasive margin were associated with significantly decreased overall mortality by 33%, 22%, and 9%, respectively (18). In addition, inverse associations were found between CTL infiltration (in tumor center and invasive margin) and the risk of colorectal cancer recurrence or death. However, only a few of these studies were population-based and adjusted for epidemiologic characteristics other than age and gender (19).

While the association between the CTL presence in the tumor environment and patient outcome is well described, there is the potential for further refinement of predictive models. For some patients, the activity of tumor CTLs may be suppressed. Functioning CTLs provide antitumor activity through production of lysosomes containing perforin and granzymes; among them, granzyme B (GZMB) is the most abundant and potent (20). However, only a few studies have specifically examined the association between CTL activity captured by GZMB and colorectal cancer patients' survival (21–24). In addition, existing data are inconsistent as to whether the association between immune cell infiltration and improved patient outcomes holds true across colorectal cancer tumor subtypes (16, 22, 25–28).

Thus, to further elucidate the role of CTLs and GZMB in colorectal carcinogenesis and prognosis, we determined (i) the correlation of these immune biomarkers in tumor epithelium and stroma with clinicopathologic, molecular, and epidemiologic characteristics and (ii) the individual and joint effect of CTLs and GZMB on all-cause and colorectal cancer–specific survival. To study these associations, we utilized data and tissue resources from the well-characterized Iowa Women’s Health Study (IWHS), a population-based cohort of older women.

Materials and Methods

Briefly, IWHS participants were women ages 55–69 years randomly sampled from the 1985 Iowa Driver’s license list (29, 30), who agreed to participate. Overall, 41,836 women completed the initial study questionnaire and were actively followed until 2011. The information about demographic, lifestyle, and anthropometric characteristics was collected at baseline and follow-up surveys in 1987, 1989, 1992, 1997, and 2004 (response rates were 91%, 90%, 83%, 79%, and 69%, respectively; ref. 29). The current study was approved by the Institutional Review Boards at University of Minnesota, Mayo Clinic Rochester, and the University of Iowa.

Colorectal cancer incidence was identified by annual linkage to the State Health Registry of Iowa, part of the Surveillance, Epidemiology, and End Results (SEER) program; the annual migration rate from Iowa was <1%; that is, the follow-up of this cohort is nearly complete (29). Colorectal cancer subtypes were categorized as proximal colon (the cecum, ascending colon, hepatic flexure, transverse colon, and splenic flexure, International Classification of Diseases for Oncology (ICD-O-3) codes C18.0, C18.2–C18.5), distal colon (descending and sigmoid colon, ICD-O-3 codes C18.6, C18.7), or rectum (rectosigmoid junction and rectum, ICD-O-3 codes C19.9, C20.9). The SEER registry also provided information on the tumor extension and size at diagnosis, the number of examined lymph nodes, and the number of positive lymph nodes, grade, and first course of treatment (surgery, radiation, chemotherapy).

Deaths of the participants in Iowa were identified through the State Health Registry of Iowa through 2011. The vital status of nonrespondents and emigrants from Iowa was ascertained via linkage to the National Death Index; colorectal cancer–specific deaths were ascertained using ICD codes that listed colorectal cancer as the underlying cause of death (ICD9: 153.0–154.1, 159.0; ICD10: C18–C20, C26.0).

Construction of tissue microarrays

For this study, we used archived, paraffin-embedded tissue specimens from incident colorectal cancer cases diagnosed in 1986–2002 that were collected as part of a focused molecular epidemiology study (CA107333). Tissue specimens were retrieved from 732 of 1,255 (58%) colorectal cancer patients, which is similar to colorectal cancer tissue retrieval rates reported by other large cohorts (31, 32). After excluding colorectal cancer patients who reported cancer at baseline (n = 146) and those with <1 day of follow-up (n = 6), tissue samples from 580 colorectal cancer patients were available for staining.

Paraffin blocks for colorectal cancer patients were serially sectioned onto 5-μm slides. The last slide was stained with hematoxylin and eosin, so that areas of neoplastic tissue (defined as >50% dysplastic cells) could be identified. For both antibodies, tonsil tissue was used as a positive control along with positive and negative colorectal tissue controls and the colorectal tissue treated with diluent. Using the marked slides as a guide, three tumor cores along with two normal colorectal tissue and liver control cores were taken from the corresponding tissue block and transferred to a TMA block. The TMAs were produced by the Mayo Clinic Pathology Research Core laboratory (Rochester, MN) using the Beecher ATA-27 automated array. From the tissue microarray, 5-μm slides were cut for hematoxylin and eosin staining and immunohistochemical staining of immune cells.

Characterization of CTLs and GZMB

Immunohistochemical analysis for CTLs (CD8+) and GZMB was performed by the Pathology Research Core at the Mayo Clinic (Rochester, MN) using the Leica Bond III Stainer (Leica). Briefly, slides were dewaxed and retrieved for 20 minutes using Bond Dewax and Epitope Retrieval 1 (citrate) for CD8 or Epitope Retrieval 2 for GZMB (Leica). The CD8 antibody (Clone 144B, Dako) and GZMB antibody (Clone GrB-7, Dako) were diluted in Bond antibody diluent (Leica) included the hydrogen peroxidase block, secondary antibody polymer, DAB, and hematoxylin. Once completed, slides were removed from the stainer and rinsed for 5 minutes in tap water. Slides were dehydrated in increasing concentrations of ethanol alcohol and cleared in xylene prior to permanent covering with xylene-based media.

An experienced gastrointestinal pathologist (T.C. Smyrk) examined each tissue core. High-quality tissue samples were available from 468 colorectal cancer patients. They were assigned an integer score to CTLs and GZMB in two tumor areas, epithelium and stroma. Mean and maximum scores were associated in a similar fashion with clinicopathologic characteristics and survival; therefore, only mean scores were used in the analyses. The following categories were created for CTL and GZMB scores: 1, nondetected;
2, mild (1–10 cells per 0.28 mm²); 3, moderate (11–29 cells per 0.28 mm²); and 4, strong infiltration (>30 cells per 0.28 mm²).

The data on molecular pathways for these IWHS colorectal tumors, including molecular subtypes, have been previously described (35, 36). Tumors were characterized as MSS, MSI-high, or -low; CIMP-high, -low, or -negative; and positive or negative for BRAF and/or KRAS mutations. On the basis of these molecular features, integrated pathways were assigned: traditional (MSS, CIMP-negative, BRAF mutation-negative, and KRAS mutation-negative), alternate (MSS, CIMP-low, BRAF mutation-negative, and KRAS mutation-positive), serrated (any MSI, CIMP-high, BRAF mutation-positive, and KRAS mutation-negative), or unassigned (36).

**Statistical analysis**

We calculated the individual epithelial and stromal tumor scores for CTL and GZMB by averaging the scores from three tumor cores per patient. We examined each immune score, separately, in epithelium and stroma: 4 categories were created for the epithelial CTL score (1, >1–2, >2–3, and >3); 3 categories, for the stromal CTL score (1, >1–2, and >2), and 3 categories each (1, >1–2, and >2) for epithelial and stromal GZMB scores. In categorizing scores, we aimed to have ≥15 colorectal cancer–specific deaths in each category. We also summarized immune scores in epithelial and stromal tumors for each biomarker (hereafter, called composite score). As epithelial and stromal scores behaved similarly in relation to the patients’ survival, the main analyses were done using composite tumor scores, categorized into quartiles for CTLs and tertiles for GZMB. We tested the distribution of immune scores across demographic, lifestyle, clinicopathologic, and molecular characteristics of colorectal cancer patients using \( \chi^2 \) test.

We used Kaplan–Meier plots to estimate survival and log-rank tests in univariable models, and Cox proportional hazards regression to compute HRs and 95% confidence intervals (CI). The main endpoints were all-cause and colorectal cancer–related death across each immune score. For all-cause mortality, participants’ follow-up ended at the earliest of death, loss to follow-up, or the end of 2011. In addition, in the analysis of colorectal cancer–related death, the participants were censored at the date of...
death due to other causes. Associations between scores and non-colorectal cancer–related death were also analyzed.

We tested the proportionality of hazards assumption by including an interaction term between each immune score and follow-up time, and detected no evidence of the assumption’s violation. However, as five-year survival is clinically important, we also analyzed mortality for the follow-up less and more than 5 years after diagnosis.

For each immune biomarker, two models were created: unadjusted model (Model 1) and Model 2, additionally adjusted for age at diagnosis, SEER stage (in situ or local, regional, or distant), tumor grade (well, moderately, poorly differentiated, or lymphoma/not stated), BMI before colorectal cancer diagnosis (continuous), and smoking history (current, former, or never). These covariates were associated with colorectal cancer patients’ mortality in the earlier IWHS and other studies and were included a priori. Of note, the missing values for stage and grade were included as separate categories, while missing values for other covariates comprised <5% and those women were excluded.

The associations were not markedly changed after further adjustment for additional variables (year of diagnosis, first course of treatment [yes/no for surgery, radiation, or chemotherapy], colorectal cancer anatomic subsite [colon proximal, colon distal or rectal cancer]; the latter two were combined), alcohol use, physical activity, hormone replacement therapy (HRT), history of diabetes, hypertension, or heart disease); and those variables were not included in the final model. Because of the existing evidence that immune infiltration is associated with molecular characteristics, we created Model 3 additionally adjusted for integrated pathway (traditional, alternate, serrated, and unassigned; ref. 36).

Furthermore, we studied the risk of all-cause and colorectal cancer–related death associated with a joint score combining CTL and GZMB composite scores: the first category of this joint score (reference) included the lowest categories of CTL and GZMB scores; the third category, the highest categories of these scores; and the second category included all other combinations. Also, we created the receiver operating characteristic (ROC) curves using the logistic regression version of Model 2 for all-cause and colorectal cancer–related death within five-year follow-up, and tested the predictive performance of the models with and without GZMB and CTL scores (presented as pseudo-continuous variables). In addition, we examined the association between each immune score and the mortality at different AJCC-TNM stages at diagnosis; our main interest was stages 2 and 3, due to the heterogeneous prognosis within these stages. The AJCC-TNM stage variable (1–4) was previously derived for colorectal cancer patients in the IWHS studies using the SEER data on tumor extension and size, the number of lymph nodes examined, and the number of positive lymph nodes.

We also conducted several exploratory analyses. We repeated the analyses for CTL and GZMB composite scores by stratifying colorectal cancer patients by tumor location (proximal and distal colorectal cancer) and molecular characteristics. To increase power in these analyses, immune scores were dichotomized at the median (≤5 and > 5 for CTL and ≤2.3 and >2.3 for GZMB; the lower category was the reference). We tested the interaction by adding a cross-product term between each composite score and the characteristics using the Wald $\chi^2$ test. Finally, we tested for selection bias by assigning a category for missing biomarker and comparing the risk of death between missing and non-missing categories in all 1,255 colorectal cancer patients. All analyses were conducted using SAS (release 9.3); all statistical tests were two-sided.

Results

In our analytic cohort of 468 colorectal cancer patients (among them, 99.6% were Caucasians) followed until 2011 (median follow-up was 8.4 years), 314 (67%) died, 144 of them from colorectal cancer (31% of the entire cohort). During the five-year follow-up, survival was 62%, which is in agreement with the SEER five-year survival for women in this age group (1). The correlations between tumor epithelial and stromal scores were 0.54 and 0.66 for CTL and GZMB, respectively. Any immunostaining with CTL cells was observed in 80.2% of epithelial and 97.2% of stromal tumors, whereas immunostaining with GZMB was observed in smaller percentage of tumors: 37.1% and 53.1% of epithelial and stromal tissues, respectively. The composite scores for CTL and GZMB (created as a sum of corresponding epithelial and stromal scores) were correlated: $r = 0.65$, which is slightly higher than $r = 0.52–0.57$ reported previously (15, 21).

Table 1 presents the distribution of composite scores across patients’ characteristics. Both composite scores were positively correlated with age at diagnosis, but not with BMI or smoking status. The highest CTL and GZMB scores were associated with proximal colon location, MSI-high, CIMP-high, BRAF mutation-positive status, and KRAS mutation-negative status (Supplementary Table S1). In addition, the percentages of distant stage, traditional, and alternate pathways were lower and the percentages of serrated pathway were higher among those with the highest GZMB and CTL scores.

In a univariable analysis, all-cause and colorectal cancer–specific survival of colorectal cancer patients were significantly better for above versus below the median of composite CTL and GZMB scores (Fig. 2A–D). Similar inverse associations for both composite scores were observed in a multivariable analysis. Compared with the lowest categories of the scores, for the highest CTL category, HRs (95%CI) were 0.53 (0.38–0.75; $P_{\text{trend}} = 0.0004$) for all-cause mortality and 0.30 (0.18–0.51; $P_{\text{trend}} < 0.0001$) for colorectal cancer mortality, whereas for the highest GZMB category: HRs (95% CI) were 0.66 (0.51–0.86; $P_{\text{trend}} = 0.002$) and 0.41 (0.27–0.63; $P_{\text{trend}} < 0.0001$) for all-cause and colorectal cancer mortality, respectively (Model 2, Tables 2 and 3). Additional adjustment for integrated pathways did not markedly change the associations (Model 3, Tables 2 and 3). Of note, given no marked difference in the findings for Models 2 and 3, all the following findings will be presented for Model 2. The associations of epithelial and stromal score with all-cause or colorectal cancer–related death behaved in parallel to the corresponding associations for composite scores (Supplementary Tables S2 and S3). There were no associations between any of the analyzed immune biomarker scores and non-colorectal cancer–related death.

In the analyses of the 5-year follow-up, the associations were similar to those observed for the total follow-up (Supplementary Table S4); no associations were observed between any of the immune scores and risk of all-cause or colorectal cancer–specific death for patients followed for ≥5 years (data not shown), but the power was limited, as most colorectal cancer–related deaths occurred within the first 5 years of follow-up. Furthermore, after stratification by stage, the inverse associations remained for colorectal cancer–related death in stages 2 and 3: for the scores
above versus below median, the risk was decreased by 52% and 62% for CTL and by 74% and 50% for GZMB, respectively (Supplementary Table S5).

In exploratory analyses, we stratified colorectal cancer patients by molecular characteristics (Supplementary Table S5). Statistically significant interactions were found between CTL score and CIMP status in relation to all-cause and colorectal cancer–related death ($P_{\text{interaction}} = 0.05$ and 0.02, respectively); decreased HRs were observed among those with CIMP low/high. Also, for colorectal cancer–related death, significant interactions were found between GZMB and colorectal cancer site ($P_{\text{interaction}} = 0.01$; lower HR for proximal tumors) and BRAF status ($P_{\text{interaction}} = 0.05$; lower HR for BRAF-positive mutation). Finally, there were no significant interactions between any composite scores and epidemiologic characteristics: age at diagnosis, smoking, alcohol, BMI, or HRT use (all $P_{\text{interaction}} > 0.1$).

In the model with the joint score based on composite CTL and GZMB, for the highest versus lowest category, HR (95% CI) for all-cause and colorectal cancer–related death were significantly decreased by 53% and 0.73%, respectively (Tables 2 and 3). Furthermore, after we simultaneously included CTL and GZMB score as dichotomous variables, all the associations were attenuated with stronger attenuation for GZMB (Tables 2 and 3). Of note, there were no interactions between these immune scores and any other variables, in the model with two immune scores, at approximately 90% specificity, the sensitivity for predicting colorectal cancer–related death was almost twice higher ($P_{\text{interaction}} = 0.56$ and 0.91 for all-cause and colorectal cancer–related death). For colorectal cancer mortality, the ROC curve areas were: 0.73 (95% CI, 0.68–0.78) without any immune score; 0.76 (95% CI, 0.72–0.81), after adding CTL only; 0.78 (95% CI, 0.78–0.82), after adding GZMB only; and 0.77 (95% CI, 0.72–0.82), after including GZMB and CTL simultaneously (Supplementary Fig. S1A). Remarkably, compared with the model without any immune score, in the model with two immune scores, at approximately 90% specificity, the sensitivity for predicting colorectal cancer–related death was almost twice higher (~50% vs. 25%), and the predictive performance was statistically significantly better ($P = 0.02$). Similar improvement of predictive

performance was observed for all-cause mortality: the ROC curve area was 0.71 (95% CI, 0.66–0.76) for the model without any immune score, and 0.73 (95% CI, 0.69–0.78) after both biomarkers were included (P = 0.04; Supplementary Fig. S1B). Finally, there was no association between the missing category of any immune scores and the risk of any death (data not shown), implying no selection bias.

**Discussion**

Among 468 postmenopausal women diagnosed with colorectal cancer, we report a statistically significant decreased risk of all-cause and colorectal cancer–related death associated with CTL and GZMB infiltration in tumor epithelium and stroma, even after accounting for stage and other confounders. For each immune score, the mortality was similar in relation to epithelial and stromal scores. Furthermore, the associations between each immune composite score and colorectal cancer–related death were observed in the patients diagnosed with stage 2 and stage 3 disease, implying that each of these scores may serve as a prognostic biomarker in those colorectal cancer patients. When both immune scores were included in the model, the predictive performance of the models for all-cause and colorectal cancer–related death significantly improved. Of note, no associations were found between immune scores and non-colorectal cancer–related death.

Consistent with previous findings (14, 20–22), we observed inverse correlations of stage with CTL and GZMB scores confirming the important role of the CTL number and activity (reflected by GZMB score) in colorectal cancer biology. Moreover, the inverse associations of CTL and GZMB scores with all-cause and colorectal cancer–related death in multivariable models suggest that both scores provide prognostic information beyond stage, which is in line with several studies for CTL (37–39) and GZMB (21, 22), although not all studies have been consistent (19, 23, 40). However, it is unclear whether the lack of significance in the latter studies was due to adjustment for stage or additional covariates such as other immune subsets and/or vascular, lymphatic, and perineural invasion. The quantitative comparison with the previous studies is complicated by the fact that many studies did not compute relative risks (i.e., constructed only Kaplan–Meier survival curves and log-ranks), while the studies presenting HRs differed in methodology, for example, had different follow-up times, adjusted for various confounders, used whole slides versus...

*Tumor CTL and GZMB composite scores were created as a sum of corresponding epithelial and stromal scores categorized into quartiles for CTL and tertiles for GZMB.
*The number of deaths is slightly different in the analyses of CTL and GZMB because of different number of available cores (n = 465 for CTL and n = 458 for GZMB; overall 468 CRC patients had tissues immunostained for CTL or GZMB).
*Model 1: Unadjusted.
*Model 2: Model adjusted for age at diagnosis, BMI, smoking status, stage, and grade at diagnosis.
*Model 3: Model 2 + integrated pathway.
in the meta-analysis: 0.64 (0.46–0.91; ref. 18), but similar to the HR of 0.43–0.47 reported in two other studies (not included into the meta-analyses; refs. 37, 38). These small discrepancies are most likely explained by the different study methodologies or various study populations.

In addition to examining the individual roles of CTL and GZMB, we examined the joint effect on survival. As expected, when these immune scores were simultaneously included in the model, there was no evidence of interaction between them, and the associations with mortality were attenuated for each biomarker, as GZMB is predominantly produced by CTLs (refs. 12, 22, 42; the correlation between GZMB and CTL scores $r = 0.65$). However, the patterns of inverse association remained for both biomarkers, with stronger associations for colorectal cancer–related death. Most likely, CTL and GZMB impact colorectal tumor through additional independent pathways. GZMB may be produced by other immune cells such as NK, dendritic, and mast cells (43), while CTLs may also kill tumor cells via the Fas-/Fas ligand pathway (44, 45).

Furthermore, in line with previous studies, we demonstrated that MSI-high tumors (vs. MSS tumors) are characterized by higher CTL (reviewed in refs. 12 and 16) and GZMB scores (21, 22, 42), which is likely explained by increased levels of frameshift mutations in MSI-high tumors leading to elevated neoantigen production and antitumor immune response (16, 28, 46). We also observed higher CTL and GZMB scores in CIMP-high (vs. CIMP low/negative) and BRAF mutation-positive (vs. negative) tumors; to our knowledge, these findings have not been previously reported for GZMB. The parallel associations for CTL and GZMB are concordant with the earlier finding that genes for Th1 adaptive immunity (including GZMB and CTLs) form a tightly regulated cluster (15). In addition, we report statistically significant interactions with CIMP status (for CTL), and BRAF mutation and subsite (for GZMB), but not with MSI status. The absence of stronger association between immune infiltration and the colorectal cancer patients’ survival for MSI-high tumors is consistent with several other studies (21, 25–27, 38), but may seem controversial, as MSI-high colorectal tumors are most strongly infiltrated with lymphocytes and associated with better prognosis in our cohort (36) and other studies (8, 10). However, the lack of survival advantage for MSI-high tumors is supported by the recent findings that the increase in CTLs and other lymphocytes in MSI-high tumors is accompanied by the production of inhibitory molecules that allow tumors to escape destruction by an immune response (46–48), which agrees with the theory of immunoediting (49). Of note, the data on the interaction with molecular factors should be interpreted with caution due to multiple comparisons and limited sample size, which increases the chance of false-positive and false-negative results. These same reasons may explain inconsistent findings for the interaction between MSI and CTLs in the previous studies (reviewed in refs. 12, 27); thus, future larger studies are needed to examine the interactions between molecular factors and immune infiltrates.

The major strength of our study is the use of a well-characterized, population-based cohort with reliable ascertainment of cancers and deaths, near complete follow-up and detailed information about epidemiologic, clinicopathologic, and molecular characteristics. One of the limitations is that we measured immune score only within the tumors, and not in the peritumoral area. However, to account for tumor heterogeneity, we examined infiltration in stromal and epithelial tissues and found no difference between these areas. Also, we averaged the scores across several tumor cores. Moreover, it has been argued that cell counting may be more reproducible within the tumor compared with the peritumoral area, and may also be more valuable in clinical practice (4). An additional limitation is that pathology core specimens were not available for all colorectal cancer patients in this cohort. However, two findings suggested no selection bias in our study: (i) there was no association between the category for missing immune scores and the risk of any death; and (ii) the participants’ demographic characteristics, exposure patterns, and tumor characteristics did not differ significantly between colorectal cancer cases with retrieved versus nonretrieved tissue specimens (35). Finally, the cohort included only white postmenopausal women, so the findings may not be generalizable to all populations.

In conclusion, our results indicate that high CTL and GZMB scores may serve as useful prognostic characteristics in colorectal cancer patients especially when accounted for simultaneously. This finding may be particularly important for colorectal cancer patients diagnosed with stages 2 and 3, for whom treatment is unclear and the more personalized approach to treatment and prognosis is needed.

Disclosure of Potential Conflicts of Interest

P.J. Limburg has ownership interest (including patents) in Exact Sciences, Inc. No potential conflicts of interest were disclosed by the other authors.
